# INDEX TO VOLUME CXXXII.

**Abbot, S. L.** A reminiscence of Dr. Holmes, 267; a case of embolism of the right femoral artery apparently from cardiac weakness, 383.

**Abbott, A. C.** The effect of the gaseous products of decomposition upon the health of animals that are compelled to respire them, 600.

**Abbott, S. W.** A report of progress in public hygiene, 359, 385.

**Abdominal surgery.** Intestinal incision and drainage in acute peritonitis, Mixter, S. J., 206, 212.

**Abscess.** A self-retaining drainage canula for preventing scar in cervical abscesses, Briggs, F. M., 433.

**Acne.** Etiology and treatment of acne, 314.

**Actinomycosis.** Actinomycosis in France, 291; a case of actinomycosis, 226, 369; two cases of actinomycosis hominis, with remarks from a clinical standpoint, Lothrop, H. A., 300; actinomycosis of the abdominal wall, Mixter, S. J., 303.

**Adler, L. H.** Colotomy and extirpation in cases of cancer of the rectum, 522.

**Advertisements.** Objectionable advertisements, 494.

**Alexander** operation. The permanent results from the Alexander operation, Blake, J. G., 410.

**Allen, H.** Doubt thrown upon the "missing link," 242.

**Anatomy.** Recent progress in anatomy, Dwight, T., 596.

**Anders, J. M.** The complications of malaria, with statistics, 548.

**Anesthesia.** The semi-centennial of anesthesia, 65; does etherization ever cause acute lobar pneumonia? Prescott, W. H., 304, 308; psychological interpretation of hysterical anesthesia, 365; an examination of some recent statistics in regard to ether and a consideration of some present methods of its administration, Blake, J. B., 559, 590.

**Aneurism.** Sudden death by rupture of thoracic aneurisms previously unrecognized, Draper, F. W., 245.

**Animal extracts,** 66.

**Animals.** Tuberculosis among our neat cattle, Osgood, F. H., 326, 336; the effect of the gaseous products of decomposition upon the health of animals that are compelled to respire them, Abbott, A. C., 600.

**Anthony, F. W.** Rape, 29, 56.

**Antitoxin.** The Berlin Medical Society on diphtheria antitoxin, 18; the antitoxin treatment in London, 21; notes on antitoxin, Winslow, K., 22; relapse and immunity after diphtheria antitoxin, 67; an epidemic of diphtheria apparently stopped by the use of antitoxin, Morrill, F. G., 80; the priority of the discovery of antitoxin, Ferran, J., 94; questions about diphtheria antitoxin, Hammond, C. B., 219; results of antitoxin treatment, 240; the antitoxin treatment for diphtheria, Withington, C. F., 249; Congressional ignorance and buffoonery respecting antitoxin, 264; the treatment of tetanus by antitoxin, 287; a State supply of diphtheria antitoxin, 315; a symposium on antitoxin, 365; the emancipation of the horse, 391; a case of laryngeal diphtheria treated by antitoxin, Lund, F. B., 484; diphtheria antitoxin and the metropolitan district, 503; the immunizing effects of antitoxin, Morrill, F. G., 633; diphtheria antitoxin, Welch, W. H., 645.

**Appendicitis,** Gay, G. W., 100.

**Asepsis** in private practice, Beck, C., 523; surgical technique of aseptic wounds, Marcy, H. O., 524.

**Ashmead, A. S.** A syphilitic lesion observed in a pre-Columbian skull, 502.

**Atkinson, I. E.** A case of suppurative pancreatitis, with necropsy, 575.

**Autopsies.** A report on the bacteriological investigations of autopsies, Wright, J. H., and Stokes, W. R., 271, 330.

**Babcock, R. H.** Enlargement of the heart without valvular disease, with special reference to treatment, 88.

**Baccelli.** Intravenous medicated injections according to Prof. Guido Baccelli's method, Hogner, R., 621, 636.

**Bacteriology.** The importance of bacteriological investigations in cases of diphtheria, McCollom, J. H., 49, 62; remarks on diphtheria, Ernst, H. C., 52, 62; a report on the bacteriological investigations of autopsies, Wright, J. H., and Stokes, W. R., 271, 330; anti-streptococcic sero-therapy, 444; treatment of malignant tumors by the toxines of the streptococcus of erysipelas, Senn, N., 521; bacteriology of water-supplies, 651.

**Baker, W. H.** Address at dedicatory exercises of the Free Hospital for Women, 121; removal of the uterine appendages for nervous diseases, 224, 234.

**Baldness.** Baldness and indigestion, 242; the cause of premature baldness, Phillips, L., 474.

**Balfour, G. W.** Heroic treatment, 218.

**Ball, J. W.** Treatment of traumatic cataract, attended with rapid swelling of the lens, 111.

**Bardeleben, von.** Ambulant treatment of fractures of the lower extremities, 563.

**Bartlett, E. W.** Neurasthenia, 348.

**Baumgarten, G.** Renal affections following influenza, 600.

**Beck, C.** Asepsis in private practice, 523.

**Bibliography.** Abbott, A. C., the principles of bacteriology, 40; Apostoli, G., travaux d'electrotherapie gynécologique, 649; Baudron, E., de l'hysterectomie vaginale, 602; Beard, G. M., sexual neurasthenia [nervous exhaustion], its hygiene, symptoms and treatment, 313; Berry, J. S., clinical medicine, 311; Bigelow, H. R., an international system of electro-therapeutics, 311; Bissell, M. T., a manual of hygiene, 389; Boston Board of Health, annual report, 444; Bourneville, recherches cliniques et thérapeutiques sur l'épilepsie l'hystérie, l'idiotie, et l'hydrocéphalie, 113; Bramwell, B., atlas of clinical medicine, Vol. III, Part I, 312; Brix, J., Pfuhl, E., and Nocht, Die Bekämpfung der Infectionskrankheiten; hygienischer Theil, 577; Brodie, C. G., dissections illustrated, 16, 649; Brown, F. H., the medical register for New England, 602; Bulkley, L. D., syphilis in the innocent, 313; Burr, C. H., a primer of psychology and mental diseases, 40; Cutler, C. W., practical lectures in dermatology, 313; Dembo, J. A., the Jewish method of slaughter compared with other methods, from the humanitarian, hygienic and economic points of view, 497; Frothingham, L., laboratory guide for the bacteriologist, 285; Hamilton, A. L., a system of legal medicine, 312; Hamilton, W. J., a text-book of pathology, systematic and practical, 625; Harold, J., and Wimmer, S. J., memoranda and tables of human anatomy, 649; Harvard College, general report, 1893-94, 168; Hovell, T. M., a treatise on the diseases of the ear, 188; Keating, J. M., and Coe, H. C., clinical gynecology, medical and surgical, 576; Keith, S., and Keith, G. W., text-book of abdominal surgery, 627; Kocher, T., operative surgery, 39; Krieger, G. L., blood-serum therapy and antitoxines, 236; Long, J. W., syllabus of gynecology, 312; McFarlane, a clinical manual, 313; Manton, W. P., syllabus of lectures on human embryology, 213; Massachusetts State Board of Lunacy and Charity, sixteenth annual report, 190; medical news visiting list for 1895, 16; Michigan, twenty-sixth annual report relating to the registry and return of births, marriages and deaths for the year 1892, 577; Morris, M., diseases of the skin, 313; Navy, report of the Surgeon-General of the United States Navy, 17; Osler, W., on chorea and choreiform affections, 65; Pilcher, J. E., first aid in illness and injury, 213; Roberts, F. T., the theory and practice of medicine, 312; Robertson, B., landmarks in gynecology, 312; Robé, G. H., text-book of hygiene, 364; Rolleston, H. D., and Kanthack, A. A., manual of practical morbid anatomy, 313; St. Lawrence Hospital for the Insane, eighth report, 337; Sayre, L. E., a manual of organic materia medica and pharmacognosy, 186; Schwarz, O., Das, Einrichtung und Betrieb von Offentlichen Schlachthöfen, 497; Stedman, T. L., twentieth-century practice, 312, 602; Stelwagon, H. W., essentials of diseases of the skin, 313; Warren, J. C., surgical pathology and therapeutics, 310; Woodhull, A. A., notes on military hygiene for officers of the line, 165; Young, J. K., a practical treatise on orthopedic surgery, 336.

**Bicycling.** Bicycle riding for women, 193; bicycling for women, Townsend, C. W., 593; bicycle saddles for women, Chadwick, J. R., 595; bicycle saddles, Townsend, C. W., 631; bicycle saddles, H. B. J., 635.

**Biography.** Baxter, M. L., 72; Bemis, J. W., 48; Blackmer, J., 396; Bowles, S. W., 196, 504; Buchanan, G., 584; Byron, J. M., 501; Campbell, H. H., 72; Campbell, P. H., 476; Charcot, J. M., 21, 370; Cornill, W. M., 424; Cuppies, G., 448; Detmold, W., 20; Disbrow, W. G., 48; Dubois, F. L., 344; Dubois, R. O., 288; Dujardin-Beaumetz, G., 504; Dunbar, H. O., 24; Durham, E., 584; Field, M. D., 265; Fisk, C. M., 120; Fitzgerald, J. S., 70; Flagg, W. H., 504; French, N., 448; Goldthwait, H., 45; Gottstein, J., 196; Greely, M. R., 448; Hagar, J., 396; Hallam, A. C., 70; Harris, J. C., 172; Hawkes, J. M., 606; Henry, M., 552; Holman, S. A., 24; Holmes, O. W., 267; Hulke, J. W., 344; Leach, T., 48; Loomis, A. L., 118, 473; Ludwig, K., 448; Meeks, 654; Minot, D. W., 48; Newell, A. D., 266; Ostrander, F. W., 141; Perkins, G. A., 532; Petronio, 372; Pillsbury, L., 144; Robinson, J. D., 556; Roof, S. W., 70; Ruschenberger, W. S. W., 344; Ryder, J. A., 344; Saltonstall, G., 654; Savory, W. S., 339; Sawyer, F. A., 173; Smith, P. C., 421; Spalding, C. F., 448; Stargis, O., 69; Sutherland, C., 504; Thiersch, K., 448; Tuke, R. H., 268; Vaughan, B. E., 266; Vogt, C., 556; Wallace, A. M., 606; Wallace, W. B., 606; Williams, H. W., 632, 654.

**Bishop, L. F.** A review of the present state of our knowledge of gout, and a discussion of its comparative frequency in America, 364; a quick method for the filtration of a small quantity of urine, 403; edema of the right upper extremity, 415.

**Blake, J. B.** An examination of some recent statistics in regard to ether, and a consideration of some present methods of its administration, 559, 590.

**Blake, J. G.** Permanent results from the Alexander operation, 410.

**Blood.** Transfusion of blood or infusion of salt solution, 526.

**Blexam, A.** A new rhinoplastic operation, 501.

**Bone.** Acute infectious processes in bone, Park, R., 425, 438; a case of pulmonary hypertrophic osteo-arthropathy, Davis, N. S., Jr., 547.
**Bonney, S. G.** Methods of treatment of empyema, 373.
**Bowditch, V. Y.** Observations upon cases having the so-called "taches bleuâtres" in the Boston City Hospital, 231.
**Bowen, J. T.** Report on dermatology, 305.
**Bowker, E. M.** End of a vaccine virus controversy, 583.
**Bradford, E. H., and Brackett, E. G.** Recent progress in orthopedic surgery, 132, 154.
**Brain.** Four cases of brain surgery, Putnam, J. J., 14; tumor of the cerebellum with bulimia and recurrent apoplectiform seizures, Eskridge, J. T., 25; unusual malformations of the brain, Wilder, B. G., 46; a consideration of some of the indications for operation in head injuries, Bullard, W. N., 73, 83; radical operation for infiltrating cerebral growths, 166; diagnosis of chronic hydrocephalus in early stages, before enlargement of the skull has occurred, 339.
**Breast.** The care of the breasts after labor, Reynolds, E., 345; tumors of the mammary gland, Rodman, W. L., 522.
**Briggs, F. M.** A self-retaining drainage canula for preventing scar in cervical abscess, 433.
**Bright's disease of a primarily infectious nature, 40.**
**Brinton, D. G.** The missing link found at last, 193.
**Bronchitis.** The abortive treatment of acute bronchitis, 238.
**Brooks, W. A., Jr.** The educational aspects of physical training, 562, 567.
**Broom, G. W.** Scientific uses of the surgical flap, 524.
**Brouardel.** Sudden death, 606.
**Brougham, H. W.** Two cases of sudden death in childbed, 53, 65.
**Buchman, A. P.** Intestinal indigestion, 89.
**Buckingham, E. M.** Medical treatment of diphtheria, 147, 159.
**Bullard, W. N.** A consideration of some of the indications for operation in head injuries, 73, 83.
**Burr, A. H.** Hydrotherapy in fevers; its rationale and technique, 547.
**Burrage, W. L.** Fish-boiler portable sterilizer, 38; cases of retrodeviation of the pregnant uterus, including a case of pregnancy in an incarcerated cornu and a case complicated by an ovarian tumor, with remarks, 360, 388; multiple fibroid of the uterus weighing four and a quarter pounds, 596.
**Burrell, H. L.** Address at the annual dinner of the Massachusetts Medical Society, 617.
**Burrell, H. L., and Cushing, H. W.** Recent progress in surgery, 488, 540, 585.
**Cesarean Section,** with the report of a case, Haven, G., 179, 188.
**California.** The invalid tourist in Southern California, Tisdale, W. M., 194.
**Calomel: a study of its physiological action and therapy in 144 cases of gastro-intestinal disorders. Is it a diuretic, *per se?*** Stewart, R. B., 544.
**Carcinoma.** The etiology of carcinoma, 138.
**Cary, C.** The cause of the exaggeration of sounds over the right upper chest both in health and disease, 626.
**Catgut.** The sterilization of catgut, Johnston, 475.
**Chadwick, J. E.** Bicycle saddles for women, 595.
**Charcot.** A fund for a bronze statue to Charcot, 21; Charcot monument fund, 423.
**Chicago.** Mortality of Chicago during the past winter, Reynolds, A. R., 422.
**Children.** Report on diseases in children, Rotch, T. M., and Wentworth, A. H., 59.
**Cholera.** Credit side of the cholera account, 142; Haffkine's inoculation against cholera, 191; the treatment of Asiatic cholera, Lee, E., 545.
**Chorea.** Quinine in the treatment of chorea, Fry, F. R., and Bliss, M. A., 89; the treatment of chorea, with especial reference to the use of quinine, Knapp, P. C., 204, 210.
**Circulatory System.** Enlargement of the heart without valvular disease, with special reference to treatment, Babcock, R. H., 88; cases of pregnancy complicated by heart disease, Sears, G. G., 176; sudden death by the rupture of thoracic aneurisms previously unrecognized, Draper, F. W., 245; three cases of spontaneous hemophilia in brothers, 263; a successful case of cardiocentesis, Sloan, A. T., 368; a case of embolism of the right femoral artery apparently from cardiac weakness, Abbot, S. L., 383; the injection of stimulants into the veins, Clark, L. P., 395; recent progress in thoracic disease, Sears, G. G., 405; a successful operation for purulent pericarditis, Eiselsberg, 447; electrolysis in the treatment of sacculated aneurism through introduced wire, with report of a successful case, Stewart, D. D., 523; cardiac instability due to acid intoxication, English, W. T., 549; the therapeutics of the senile heart, Pattee, A. F., 549; etiology of idiopathic hypertrophy of the heart, Whittaker, J. T., 624; the transmission of mitral diastolic murmurs, Griffith, J. P. C., 625; the use of the differential stethoscope in the study of cardiac murmurs, Smith, A., 626.
**Clark, L. P.** The injection of stimulants into the heart-walls, 395.
**Clarke, H. P.** Report of a case of unilateral cystic degeneration of the kidney complicated by tubercular peritonitis, 10.
**Climate.** Sanitary climatology, 92.
**Cline, L. C.** Some observations on sore throat due to concretions in the tonsils, 111.
**Cocaine.** Another case of cocaine poisoning, Schede, 582.
**Coggin, D.** Collodion in plastic operations, 531.
**Coley, W. B.** The treatment of inoperable malignant tumors with erysipelas and prodigious toxins, 95.
**Collins, L. C.** A case of tabes associated with unilateral reflex iridoplegia and post-hemiplegic athetosis, 417.
**Collodion** in plastic operations, Coggin, D., 531.
**Congress** of Internal Medicine, 442.
**Coolidge, A., Jr.** Recent progress in laryngology, 186.
**Councilman, W. T.** Recent progress in pathology, 256, 282.
**Courtney, S. E.** Report of four cases of puerperal eclampsia occurring in the Boston City Hospital, 486, 490.
**Craig** colony for epileptics, 239.
**Currie, J. Z.** Puerperal septicemia, with case, 612.
**Curtis, F. G.** "Scarlet fever with especial reference to contagion and prophylaxis," 71.
**Cushing, E. W.** Remote results of the removal of the uterus and ovaries, 151, 163.
**Cutaneous System.** A mechanical treatment of eczema in children, Hall, H. J., 59; a case of frog-skin grafting, Smith, G. S., 79; report on dermatology, Bowen, J. T., 305; the etiology and treatment of acne, 314.
**Cutler, E. G.** Hemorrhagic pancreatitis, 354, 361.
**Daly, W. H.** Malaria a water-borne disease, 68.
**Dana, C. L.** A case of acute poliomyelitis in a hen, 14.
**Dandridge, N. P.** Rose's operation for trigeminal neuralgia, 397, 412.
**Davenport, F. H.** Report on progress in gynecology, 461.
**Davis, N. S., Jr.** A case of pulmonary hypertrophic osteo-arthropathy, 547.
**Death.** Sudden death, Brouardel, 606; the causes of sudden death, Durell, T. M., 640.
**Deaver, J. B.** Appendicitis, 520.
**Delfarmo, W. B.** What advance has been made in the radical cure of hernia? 520.
**Degeneracy** in literature, 286.
**Denny, C. P.** A case of persistent hematuria, 183.
**Denver.** A letter from Denver, Edson, C. E., 369.
**Derby, H.** Hints concerning the performance of the operation for the extraction of senile cataract, being a record of personal experience, 97.
**Diabetes.** The pathogeny of diabetes, 114.
**Diagnosis.** Deferred diagnosis, McCallum, O. F., 9.
**Digestive System.** Case of unilateral cystic degeneration of the kidney complicated by tubercular peritonitis, Clarke, A. P., 10; successful laparotomies for perforating typhoid and perforating gastric ulcers, 42; intestinal indigestion, Buchman, A. P., 89; appendicitis, Gay, G. W., 100; a case of congenital diaphragmatic hernia, Sears, G. G., 101; some observations on sore throat due to concretions in the tonsils, Cline, L. C., 111; the pathogeny of diabetes, 114; the surgical treatment of general peritonitis, 115; a new journal devoted to the digestive organs, Friedenwald, J., 171; the microbiology of acute peritonitis, 189; total resection of the stomach, Langenbuch, 193; intestinal incision and drainage in acute peritonitis, Mixter, S. J., 206, 212; the stomach test in murder trials, Liebmann, G., 207; baldness and indigestion, 242; clinical features and treatment of external piles, 269; two cases of dermoid cyst of the ovary, involving the large intestine, removal of cysts, resection of intestine and end-to-end suture, recovery, Richardson, M. H., 399, 408; three cases of hereditary rumination, Runge, E. C., 515; what advance has been made in the radical cure of hernia? DeGarmo, W. B., 520; appendicitis, Deaver, J. B., 520; is total extirpation of the rectum ever justified? Matthews, J. M., 522; colotomy and extirpation in cases of cancer of the rectum, Adler, J. M., 522; ileus, Murphy, J. B., 523; surgical treatment of hemorrhoids, Trowbridge, E. H., 536; the differential diagnosis of cholelithiasis, Webster, G. W., 574; a new method of dissection in the investigation of functional disorders of digestion, Webster, G. W., 575; a case of suppurative pancreatitis, with necropsy, Atkinson, I. E., 575.
**Dinner** to three new medical baronets, 447.
**Diphtheria.** The Berlin Medical Society on diphtheria antitoxin, 18; the antitoxin treatment in London, 21; the importance of bacteriological investigations in cases of diphtheria, McCollom, J. H., 49, 62; remarks on diphtheria, Ernst, H. C., 52, 62; relapse and immunity after diphtheria antitoxin, 67; an epidemic of diphtheria apparently stopped by the use of antitoxin, Morrill, P. G., 80; medical treatment in diphtheria, Mason, A. L., 145, 159; medical treatment of diphtheria, Buckingham, E. M., 147, 159; a clinical and experimental study of the leucocytosis of diphtheria, Morse, J. L., 228, 252; the antitoxin treatment for diphtheria, Withington, C. F., 249; a State supply of diphtheria antitoxin, 315; diphtheria, intubation, nasal, Swasey, Stearns, S. H., 484; bacteria in diphtheria, Jacobson, W., 422; observations on diphtheria, McCollom, J. H., 449, 464; a case of laryngeal diphtheria treated by antitoxin, Lund, F. B., 484; the immunizing effects of antitoxin, Morrill, P. G., 633; diphtheria antitoxin, Welch, W. H., 645.
**Doonan, S.** Address at dinner of the Massachusetts Medical Society, 620.
**Draper, F. W.** Recent progress in legal medicine, 232; sudden death by the rupture of thoracic aneurisms previously unrecognized, 245.
**Durell, T. M.** The causes of sudden death, 640.
**Dwight, T.** Recent progress in anatomy, 596.
**Ear.** Remarks upon stapedectomy, Jack, F. L., 34, 39; the removal of the auditory ossicles for the relief of chronic deafness and other abnormal conditions, Heflebower, R. C., 111; Halle and the aural clinic of Professor Schwartze, Richards, G. L., 275.
**Easton, E. G.** Leucocytosis in poisoning by illuminating-gas, 256.
**Eczema.** A mechanical treatment of eczema in young children, Hall, H. J., 59.
**Edema** of the right upper extremity, Bishop, L. F., 415.
**Editorials.** Report of the Surgeon-General of the United States Navy, 17; the insane asylums on Ward's Island, New York, 18; the Berlin Medical Society on diphtheria antitoxin, 18; the position of the Philadelphia Hospital trustees, 18; Bright's disease of a primarily infectious nature, 40; successful laparotomies for perforating typhoid and perforating gastric ulcers, 42; the semi-centennial of Harvard, 63; animal extracts, 66; relapse and immunity after diphtheria antitoxin, 67; hypnotism and murder, 67; gonorrheal infection of the nervous system, 90; report on New York tenement-houses, 91; a chair of anatomy, physiology and hygiene at West Point, 92; sanitary climatology, 92; the pathogeny of diabetes, 114; the surgical treatment of general peritonitis, 115; castration for hypertrophy of the prostate, 116; the etiology of carcinoma, 138; the bill for the reorganization of the *personnel* of the navy, 139; radical operation for infiltrating cerebral growths, 166; the annual report of Harvard College, 1893-94, 168; the microbiology of acute peritonitis, 189; the sixteenth annual report of the Massachusetts State Board of Lunacy and Charity, 190; Haffkine's inoculation against cholera, 191; the ambulant treatment of fractures of the lower extremity, 213; a metropolitan water-supply, 215; nervous diseases and modern life, 215; the abortive treatment of acute bronchitis, 238; Craig colony for epileptics, 239; results of antitoxin treatment, 240; three cases of spontaneous hemophilia in brothers, 263; Congressional ignorance and buffoonery respecting

**antitoxin**, 264; **degeneracy** in literature, 286; the treatment of **tetanus** by antitoxin, 287; the relation of heredity to insanity and idiocy, 314; etiology and treatment of acne, 314; a State supply of diphtheria antitoxin, 315; report of the St. Lawrence Hospital for the Insane, 337; an epidemic of leprosy in Riga, 339; diagnosis of chronic hydrocephalus in early stages, before enlargement of the skull has occurred, 339; psychological interpretation of hysterical anesthesia, 365; inspection of meat, 366; on hereditary cerebellar ataxia, 389; the emancipation of the horse, and its dangers, 391; scientific research in medicine, 419; the thirteenth Congress of Internal Medicine, 442; anti-streptococcus sero-therapy, 444; annual report of the Boston Board of Health, 444; a history of the Pennsylvania Hospital, 470; temperance teaching in the public schools, 471; the vital statistics of England for 1894, 472; the British royal commission on tuberculosis, 498; the navy medical service, 499; transfusion of blood or infusion of salt solution, 526; a report of one thousand excisions of the thyroid, 527; the Keeley cure *versus* the rational treatment of inebriety, 550; a dangerous popular antiseptic, 551; experimental myelitis, 578; excision of the sterno-mastoid muscle for wry-neck, 579; a new theory regarding the physiology of the nerve centres, 603; a medical-practice law in Rhode Island, 604; the alleged exaltation of faculty in "second states," 627; should a preliminary course in the liberal arts be required for admission to our medical schools, 629; the treatment of tetany by thyroid extract, 650; the bacteriology of water-supplies, 651.

**Edson, C. E.** Letter from Denver, 369.

**Education.** New York Medical College, 45; a chair of anatomy, physiology and hygiene at West Point, 92; the annual report of Harvard College, 1893–4, 168; temperance teaching in the public schools, 471; should a preliminary course in the liberal arts be required for admission to our medical schools? 629.

**Eiselsberg.** A successful operation for purulent pericarditis, 447.

**Elliot, J. W.** Surgical treatment of pancreatitis, with a case, 351, 361.

**Embryos.** Human embryos desired, Minot, C. S., 243.

**Empyema.** Metapneumonic empyema, Withington, C. F., 5, 12; methods of treatment of empyema, Bonney, S. G., 373.

**English, W. T.** Cardiac instability due to acid auto-intoxication, 549.

**Epilepsy.** Craig colony for epileptics, 239.

**Ernst, H. C.** Remarks on diphtheria, 52, 62.

**Eskridge, J. T.** Tumor of the cerebellum, with bullmia and recurrent apoplectiform seizures, 25.

**Ether.** An examination of some recent statistics in regard to ether and a consideration of some present methods of its administration, Blake, J. B., 509, 530.

**Eye.** Recent progress in ophthalmology, Standish, Myles, 11; hints concerning the performance of the operation for the extraction of senile cataract, being a record of personal experience, Derby, H., 97; treatment of traumatic cataract attended with rapid swelling of the lens, Ball, J. M., 111; the dangers in removing foreign bodies from the cornea, Harvey, N. D., 130; a six-day record of ophthalmic surgery, Hall, G. C., 422; some of the simpler tests for detecting errors of refraction and insufficiencies of the ocular muscles, Proctor, F. I., 481.

**Femur.** Removal of head of femur for dislocation into lesser sciatic notch, Ricketts, B. M., 110.

**Fenwick, E. H.** Effects of castration upon the enlarged prostate, 318.

**Ferran, J.** The priority of the discovery of antitoxin, 94.

**Fever.** Hydrotherapy in fevers, its rationale and technique, Burr, A. H., 547.

**Food.** Inspection of meat, 366.

**Foot.** Flat-foot, Ricketts, B. M., 524; a report of cases in which there was obliteration of the anterior transverse arch of the foot, Goldthwait, J. E., 564, 572.

**Forbes, S. F.** Excision of the knee-joint with report of a case of complete dislocation of the knee of nine years' standing, with especial reference to methods of fixation, 524.

**Fractures.** The ambulant treatment of fractures of the lower extremity, 213; fracture of the humerus from an unusual cause, Monks, G. H., 281; a simple method of dressing fractures of the extremities auxiliary to the bandage, Link, J. E., 525; deformities following fractures of the shafts of bones, Manley, T. H., 525; another case of "fracture of the humerus from an unusual cause," Taylor, J. M., 554; ambulant treatment of fractures of the lower extremities, von Bardeleben, 582.

**Free Hospital for Women.** Address at dedicatory exercises, Baker, W. H., 121.

**Friedenwald, J.** A new journal devoted to the digestive organs, 171.

**Frog-Skin.** A case of frog-skin grafting, Smith, G. S., 79.

**Fry, F. R., and Bliss, M. A.** Quinine in the treatment of chorea, 89.

**Furbringer.** A case of tubercular meningitis, diagnosis by lumbar puncture, recovery, 21.

**Gage, H.** Movable kidney, 520.

**Galactopathy.** Wigglesworth, E., 219.

**Gas.** Leucocytosis in poisoning by illuminating-gas, Eaton, W. G., 256.

**Gaston, J. McF.** Radical interference in diseases of the chest, 521.

**Gavin, M. F.** A case of castration for hypertrophied prostate, 437.

**Gay, G. W.** Appendicitis, 100.

**Generative System.** Recent progress in genito-urinary surgery, Watson, F. S., 35; myoma of the uterus, Porter, C. B., 62; the treatment of uterine fibroids with report of cases, Wheeler, L., 103; castration for hypertrophied prostate, Ricketts, B. M., 110; laparotomy for pelvic disease no longer a necessity, Sutton, R. S., 112; on some of the clinical features of primary tuberculosis of the genito-urinary organs, Watson, F. S., 121, 135; congenital phimosis, 142; remote results of the removal of the uterus and ovaries, Cushing, E. W., 151, 163; ultimate results of the removal of ovaries and tubes, Mumford, J. G., 153, 164; multilocular cyst of the ovary, double ovariotomy, recovery, Phelps, J. S., 185; the surgical treatment of fibroid tumor of the uterus, Homans, J., 221, 258; removal of the uterine appendages for nervous diseases, Baker, W. H., 224, 234; effects of castration upon the enlarged prostate, Fenwick, E. H., 318; a fibroid tumor of the uterus, Warren, J. C., 361; report of cases of castration for the relief of prostatic hypertrophy, with remarks, Watson, F. S., 378; two cases of dermoid cyst of the ovary involving the large intestine, removal of cysts, resection of intestine, and end-to-end suture, recovery, Richardson, M. H., 399, 408; the permanent results from the Alexander operation, Blake, J. G., 410; a case of castration for hypertrophied prostate, Gavin, M. F., 437; vaginal hysterectomy after Martin's method, Lothrop, H. A., 438; report on progress in gynecology, Davenport, F. H., 461; the radical cure of hydrocele, Hawley, D. C., 520; transverse septa of the vagina, Stone, A. K., 533, 543; case of septum of the vagina, Torrey, S. W., 539; pelvic inflammations, Green, C. M., 541; multiple fibroid of the uterus weighing four and a quarter pounds, Barrage, W. L., 596; abdominal hysterectomy in the treatment of septic pelvic disease and for cancer of the os uteri, Irish, J. C., 615.

**Goldthwait, J. E.** A section of a spine, 360; a report of cases in which there was obliteration of the anterior transverse arch of the foot, 564, 572.

**Gonorrhœa.** Acute gonorrheal rheumatism, Lilienthal, H., 75; gonorrheal infection of the nervous system, 90.

**Gout.** A review of the present state of our knowledge of gout and a discussion of its comparative frequency in America, Bishop, L. F., 364.

**Gray, L. C.** Palmus, 416.

**Green, C. M.** Pelvic inflammations, 541.

**Greenhalge, F. T.** Address before the Massachusetts Medical Society, 617.

**Griffith, J. P. C.** The transmission of mitral diastolic murmurs, 625.

**Gun-shot Wounds.** Successful laparotomy for revolver wound of the abdomen in a pregnant woman, 342; deflection of bullets by tissues, Hall, J. N., 502.

**Gynecology.** Report on progress in gynecology, Davenport, F. H., 461.

**Haffkine's** inoculation against cholera, 191.

**Hair.** Baldness and indigestion, 242.

**Hall, G. C.** A six-day record of ophthalmic surgery, 422.

**Hall, H. J.** A mechanical treatment of eczema in young children, 59.

**Hall, J. N.** Deflection of bullets by tissues, 502.

**Halle and the aural clinic of Professor Schwartze, Richards, G. L., 275.**

**Hammond, C. B.** Questions about diphtheria antitoxin, 219.

**Hare, C. H.** A case of eclampsia, death, 487, 490.

**Harvey, N. D.** The dangers in removing foreign bodies from the cornea, 130.

**Haven, G.** Cæsarean section, with report of a case, 179, 188.

**Hawley, D. C.** The radical cure of hydrocele, 520.

**Head.** The surgical treatment of injuries of the head, Parker, C. B., 110.

**Health.** The report of a committee on establishing a national department of public health, 495.

**Heat prostration, an analysis of one hundred cases occurring in thirteen consecutive years, 511.**

**Heflebower, R. C.** The removal of the auditory ossicles for the relief of chronic deafness and other abnormal conditions, 131.

**Hemophilia.** Three cases of spontaneous hemophilia in brothers, 263.

**Hemorrhoids.** Clinical features and treatment of external piles, Otis, W. J., 269; surgical treatment of hemorrhoids, Trowbridge, E. H., 536.

**Hernia.** A case of congenital diaphragmatic hernia, Sears, G. G., 107; what advance has been made in the radical cure of hernia? DeGarmo, W. B., 520.

**Heroic treatment, Balfour, G. W., 219.**

**Higgins, F. A., and Ogden, J. S.** Traumatic glycosuria, 197.

**Hingston, W. H.** Address at dinner of the Massachusetts Medical Society, 621.

**Hogner, R.** Criticism on the usual method of measurement of chest-expansion in life insurance examinations, and stethokyrtographical studies of the bilateral expansion of the chest, 453; intravenous saline injections according to Prof. Guido Baccelli's method, 621, 636.

**Hollister, J. C.** New departure in therapeutics, 544.

**Holmes, O. W.** A characteristic letter from Dr. Holmes, 22.

**Holton, H. D.** The address on State medicine, 496.

**Holyoke, W. C.** Some cases of scarlet fever with especial reference to contagion and prophylaxis, 32.

**Homans, J.** The surgical treatment of fibroid tumors of the uterus, 221, 258; anatomical specimens, 258.

**Hospital.** Ethics of the metropolitan surgeon and the metropolitan hospital, 118; address at dedicatory exercises of the Free Hospital for Women, Baker, W. H., 121.

**Hydrocele.** The radical cure of hydrocele, Hawley, D. C., 520.

**Hygiene.** Report of progress in public hygiene, Abbott, S. W., 359, 385.

**Hypnotism and murder, 67.**

**Ileus.** Murphy, J. B., 523.

**Infectious Disease.** The immunity conferred by an attack of infectious disease, Maiselis, 46.

**Instruments and Apparatus.** Fish-boiler portable sterilizer, Burrage, W. L., 38; the value of the stomach-tube in feeding after intubation, based upon twenty-eight cases, also its use in post-diphtheritic paralysis, Morrison, W. A., 127, 137; Orthman's instrument in vaginal fixation of the uterus, Sherman, F. M., 159; a self-retaining drainage canula for preventing scar in cervical abscesses, Briggs, F. M., 433.

**Irish, J. C.** Abdominal hysterectomy in the treatment of septic pelvic disease and for cancer of the os uteri, 615.

**Ishiguro.** The care of the sick and wounded in the Japanese army, 266.

**Jack, F. L.** Remarks on stapedectomy, 34, 39.

**Jackson, J. M.** Symphyseotomy, 181, 188.

**Jackson, W.** Nuclein in diphtheria, 422.

**Japan.** The care of the sick and wounded in the Japanese army, Ishiguro, 266.

**Johnston.** The sterilization of catgut, 475.

**Jurisprudence.** Hypnotism and murder, 67; brief mention of a

**few cases of nervous and mental malady involving medico-legal questions, Rosse, I. C., 173; the stomach test in murder trials, Liebmann, G., 207; recent progress in legal medicine, Draper, F. W., 232; persistent attempts at self-destruction, a remarkable method of suicide, Morrow, C. H., 334; the murder of James Farrar, Mead, J. A., 402, 418; the causes of sudden death, Durell, T. M., 640.**

**Keefe, J. W.** A case of subcutaneous suture of a fractured patella, 10.

**Keeley cure** *versus* the rational treatment of inebriety, 550.

**Keen, W. W.** Dogs, women, men, humanity, 290.

**Kellogg, D. S.** A long period of fecundity, 554.

**Kellogg, J. H.** New methods of precision in the investigation of functional disorders of digestion, 575.

**Kenwood.** Milk-borne throat illness, phenomenal epidemic, 631.

**Knapp, P. C.** Recent progress in diseases of the nervous system, 81, 108; the treatment of chorea with especial reference to the use of quinine, 204, 210; address before American Neurological Association, 557.

**Knee.** Tumor albus of the knee-joint, Wirt, W. E., 111; resection of the knee for separation of the lower epiphysis of the femur, Meisenbach, A. H., 111; excision of the knee with report of a case of complete dislocation of the knee of nine years' standing, with especial reference to methods of fixation, Forbes, S. F., 524.

**Langenbuch.** Total resection of the stomach, 193.

**Lanphear, E.** Bone and joint tuberculosis the future field of litigation against railways, 87.

**Laparotomy.** Successful laparotomies for perforating typhoid and perforating gastric ulcers, 42; laparotomy for pelvic diseases no longer a necessity, Sutton, R. S., 112; successful laparotomy for revolver wound of the abdomen in a pregnant woman, 342.

**Larynx.** Recent progress in laryngology, Coolidge, A., Jr., 186.

**Lead** encephalopathy, with report of a case, Roussel, A. E., 550.

**Lee, E.** The treatment of Asiatic cholera, 245.

**Leffingwell, A.** The American Humane Association and vivisection, 343; a reply to Prof. H. C. Wood, 371; Dr. Leffingwell to Dr. Wood, 423.

**Legal Medicine.** Recent progress in legal medicine, Draper, F. W., 232.

**Legislation.** Recent medical legislation in Minnesota, 530.

**Leprosy.** An epidemic of leprosy in Riga, 339.

**Leszynsky, W. M.** An opening in the skull, 416.

**Leucocytosis.** A clinical and experimental study of leucocytosis of diphtheria, Mosher, L., 228, 252; leucocytosis in poisoning by illuminating gas, Eaton, R. G., 256.

**Leucomain** poisoning. Rachford, B. K., 599.

**Liebmann, G.** The stomach test in murder trials, 207.

**Lilienthal, H.** Acute gonorrheal rheumatism, 75.

**Link, J. E.** A simple method of dressing fractures of the extremities auxiliary to the bandage, 525.

**Literature.** Degeneracy in literature, 286.

**Loeb, H. W.** Double nasal atresia due to small-pox, 112.

**Lothrop, H. A.** Two cases of actinomycosis hominis, with remarks from a clinical standpoint, 300; vaginal hysterectomy after Martin's method, 458.

**Lovett, R. W.** The flaxseed-meal poultice as a sterile dressing, 329.

**Lund, F. B.** A case of laryngeal diphtheria treated by antitoxin, 484.

**Lydston, G. F.** Remarks on the relation of residual urine to vesical irritation, especially in prostatics, 112.

**McCallum, O. F.** Deferred diagnosis, 9.

**Maclean, D.** Address at annual meeting of the American Medical Association, 493.

**McCollom, J. H.** The importance of bacteriological investigations in cases of diphtheria, 49; observations on diphtheria, 449, 464.

**Maisells.** The immunity conferred by an attack of infectious disease, 46.

**Malaria.** Malaria a water-borne disease, Daly, W. H., 88; the histogenesis of the plasmodium malariæ, Rogers, F. A., 125; malarial disorders in large cities with especial reference to Chicago, 494; the complications of malaria, with statistics, Anders, J. M., 548.

**Mallory, F. B.** A case of actinomycosis, 296.

**Manley, T. H.** Deformities following fractures of the shafts of bone, 525.

**Marcy, H. O.** Modern surgical technique, 113; surgical technique of aseptic wounds, 524.

**Marion, H. E.** Clinical chart of a child with mild typhoid fever, 64; early curetting in puerperal sepsis, 558.

**Martin, F. C.** "End of a vaccine virus controversy," 607.

**Mason, A. L.** Medical treatment in diphtheria, 145, 159.

**Materia Medica and Therapeutics.** The Berlin Medical Society on diphtheria antitoxin, 18; the antitoxin treatment in London, 21; notes on antitoxin, Winslow, K., 22; serum-therapy in Paris, Roeth, A. G., 22; animal extracts, 66; relapse and immunity after diphtheria antitoxin, 67; quinine in the treatment of chorea, Fry, F. R., and Bliss, M. A., 89; the treatment of inoperable malignant tumors with erysipelas and prodigiosus toxins, Coley, W. B., 95; steam as a hemostatic, Snegirew, W. F., 142; galactopathy, Wigglesworth, E., 219; cold in the treatment of pneumonia, Mays, T. J., 343; the injection of stimulants into the heart-walls, Clark, L. P., 395; nuclein in diphtheria, Jackson, W., 422; sulphonal and trional compared, Webber, S. G., 516; new departures in therapeutics, Hollister, J. C., 544; calomel, a study of its physiological action and therapy in 144 cases of gastro-intestinal disorders. Is it a diuretic, *per se?* Stewart, W. B., 544; hydrotherapy in fevers, its rationale and technique, Burr, A. R., 547; the effects of pure oxygen introduced into the body in various ways upon the hemoglobin, Preston, G. J., 549; a dangerous popular antiseptic, 551; leucocytes and protonuclein, Summers, T. O., 576.

**Matthews, J. M.** Is total extirpation of the rectum ever justified? 522.

**Mayo.** A fatal case of poisoning by Mayo's vegetable vapor, Sweetsir, F. E., 107.

**Mays, T. J.** Cold in the treatment of pneumonia, 343.

**Mead, J. A.** The murder of James Farrar, 402, 418.

**Meat.** Inspection of meat, 366.

**Meisenbach, A. H.** Resection of the knee for separation of the lower epiphysis of the femur, 111.

**Mercer, A. C.** Photo-micrograph *versus* micro-photograph, 71.

**Microscopy.** Photo-micrograph *versus* micro-photograph, Mercer, A. C., 71; micro-photographs, 96.

**Mind.** The city insane asylums on Ward's Island, New York, 18; the mental symptoms of cerebral syphilis, a clinical study, Norbury, F. P., 116; the relation of heredity to insanity and idiocy, 314; asylum physicians and commitment certificates, Stedman, H. R., 321; report of the St. Lawrence Hospital for the Insane, 337; the alleged exaltation of faculty in "second states," 647; report on mental diseases, Stedman, H. R., 642.

**Minnesota.** Recent medical legislation in Minnesota, 530.

**Minot, C. S.** Human embryos desired, 243.

**"Missing Link."** The missing link found at last, Brinton, D. G., 193; doubt thrown upon the "missing link," Allen, H., 242.

**Mixter, S. J.** Intestinal incision and drainage in acute peritonitis, 206, 212; actinomycosis of the abdominal wall, 303.

**Monks, G. H.** Fracture of the humerus from an unusual cause, 281.

**Morrill, F. G.** An epidemic of diphtheria apparently stopped by the use of antitoxin, 80; the immunizing effects of antitoxin, 633.

**Morrison, W. A.** The value of the stomach-tube in feeding after intubation, based upon twenty-eight cases, also its use in post-diphtheritic paralysis, 127, 137.

**Morrow, C. H.** Persistent attempts at self-destruction, a remarkable method of suicide, 334.

**Morse, J. L.** A clinical and experimental study of leucocytosis of diphtheria, 228, 252.

**Mumford, J. G.** Ultimate results of the removal of ovaries and tubes, 153, 164.

**Murphy, J. B.** Ileus, 523.

**Myelitis.** Experimental myelitis, 578.

**Navy.** Report of the surgeon-general of the United States Navy, 17; the bill for the reorganization of the *personnel* of the navy, 139; pay of naval medical officers, 494; the navy medical service, 499.

**Nervous System.** Four cases of brain surgery, Putnam, J. J., 14; exhibition of micro-photographs of nerve cells (Golgi's stains), Starr, M. A., 14; a case of acute poliomyelitis in a hen, Dana, C. L., 14; some of the important aspects of the therapeutics of diseases of the nervous system, Putnam, J. J., 15; trephining in meningitis, Ricketts, B. M., 21; a case of tubercular meningitis, diagnosis by lumbar puncture, recovery, Fürbringer, 21; a mindless frog, Wilder, B. G., 22; tumor of the cerebellum with bulimia and recurrent apoplectiform seizures, Eskridge, J. T., 25; a consideration of some of the indications for operation in head injuries, Bullard, W. N., 73, 83; a case of fracture of the base of the skull, probably involving the cavernous sinus, operation, recovery, Watson, F. S., 78, 83; recent progress in diseases of the nervous system, Knapp, P. C., 81, 107; reflex irritation as a cause of disease, Walker, E. G., 89; gonorrheal infection of the nervous system, 96; trephining for pressure as a result of acute cerebral meningitis, Ricketts, B. M., 110; radical operation for infiltrating cerebral growths, 166; brief mention of a few cases of nervous and mental malady involving medico-legal questions, Rosse, I. C., 173; the treatment of chorea, with especial reference to the use of quinine, Knapp, P. C., 204, 210; nervous diseases and modern life, 215; removal of the uterine appendages for nervous diseases, Baker, W. H., 224, 234; Craig colony for epileptics, 239; the treatment of tetanus by antitoxin, 287; neurasthenia, Bartlett, B. ## TRAINED NURSING.[1]

BY A. WORCESTER, A.M., M.D., WALTHAM, MASS.

LADIES AND GENTLEMEN: — I myself shall have a pleasant evening, for I have the chance of speaking upon a subject in which I am very much interested, and I take it that no pleasure can quite equal that.

I believe not only that we owe a great debt to professional nursing, but also that in no other direction can the medical profession do more to advance its own interests, and at the same time to alleviate the sum total of human suffering, than by giving attention to the nursing profession. When I think of the constantly increasing obligations that we are under to nurses, it seems to me rather strange that no more attention is paid to the question; and I think it particularly fitting in a graduate course at the Medical School that one of the younger graduates should give his testimony to this indebtedness, and point out what we can do to help the nursing profession along.

But before trying to point out what can be done by physicians to advance the interests of nurses we should follow our usual course of looking at the family history, and study the origin and development of nursing. When we hunt back for the history of our own profession we lose it of course in the Dark Ages, and we find that physicians are bound by traditions and inheritances, the origin of which are so obscure that we hardly know what reason we have for much that we do. With the nursing profession, on the other hand, its development is so recent that all has been acquired within the memory of men now living.

In 1822 a young German clergyman journeyed on foot into his parish of Kaiserwerth on the Rhine to save his poor parishioners the expense of his journey. After a few weeks' residence in his new parish he lost his church, which was sold for a debt of one of his parishioners. He then set out on foot through Belgium, the Rhenish Provinces and England, soliciting funds to regain his church; and on that journey he carried out his heart's desire of studying asylum and prison and hospital management with the view of bringing back to his parish all that was then known in the world. When he did come back to Kaiserwerth, he brought not only the gold to redeem his church, but what was of far more value, an intimate acquaintance with the methods of alleviating suffering. In 1833 in a little summer-house in his garden he founded the first nurses' training-school in the world. A couple of women agreed to devote their lives to this profession, which as yet existed only in the mind of Pastor Fliedner. In 1836 a new building was provided, and in 1886 when the semi-centennial was celebrated, there were sixty such houses and six thousand such women acknowledging their common parentage and inspiration.

In 1851 a young woman of England, determined upon doing all the good that could be done on earth, went to Kaiserwerth to learn how to relieve sickness and suffering. That was Florence Nightingale. In 1854, during the Crimean War, when the reports of the suffering of the English were so terrible, she asked for volunteers to go to the front to take care of the sick. About one hundred volunteered. That was the first corps of nurses in service in time of war. Hardly any one is ignorant of that service, and Florence Nightingale's name is immortal. Upon her return from the Crimea, so great was the gratitude of the English nation for what she had done, that a fund of fifty thousand pounds was subscribed for her personal benefit, but she devoted it to the foundation of the first training-school for nurses in England, in connection with St. Thomas's Hospital.

In spite of the fact that during our Civil War there was exhibited such tremendous need of nurses' services, there were no trained nurses in America until 1872.

In 1865 the New England Hospital for Women and Children announced as one of its purposes the training of nurses; but it was not till 1872 that the first class was started.

There had been before this several sporadic attempts at teaching nursing. In the New York Hospital there is a tablet stating that in 1798 Dr. Valentine Seaman began giving systematic instruction in nursing. In 1861, in the Women's Hospital in Philadelphia, instruction was begun, but not even there was systematic instruction begun until 1872.

We owe what we have of trained nursing in America more than to any one else to the late Dr. Susan Dimmock. She was full of such enthusiasm as the world seldom sees. She fought down in Boston the prejudice against young women of good families and otherwise fair opportunities entering such work. But I think we may say that the first training-schools at the New England Hospital and at the Women's Hospital in Philadelphia, judged by the present standard of nursing, can hardly be counted as regular training-schools, because nurses there were trained only in the care of women and children. In 1873, when the school was started at the Massachusetts Hospital, it was distinctly understood that the nurses would have employment only in the care of women and children. It was not until some years after that they were put in charge of the male wards. But so rapid has been the advance in the foundation of training-schools within these last few years, that when in the Section upon Nursing in the Chicago Conference last year the question of the numerical strength of the nursing profession was under consideration, there were reports of 150 schools, 3,250 students and nearly 5,000 graduates upon their rolls. Training-schools are now multiplying very fast; and it is easy to foresee that the time is not far distant when no considerable-sized town will be without its training-school.

The profession, however, is not nearly so far advanced here as it is abroad. In England great strides have been taken under the direct inspiration of Florence Nightingale and with the accession of strength that came from the glorious services of her early pupils, as, for instance, Mrs. Dacre Craven, who was sent in 1870 to Metz by the Empress Frederick and the Princess Alice, and who with a corps of volunteer nurses took charge of those typhus-fever wards and did most heroic service. Their hospital training-schools are better than ours, if for no other reason than that they require a longer period of training. It takes three years for the nurse in England to gain her diploma. The profession is further advanced, again, because in England a close relationship is kept between the graduate nurse and her school in after life; and, again, better than the condition of things in America, because whenever a nurse tires out, she is

[1] A lecture given in the Graduates' Course at the Harvard Medical School, October 25, 1894.

there taken care of and finally can avail herself of a pension fund for nurses, which so far has not been successfully established here.

In Germany the Protestant deaconesses have similar advantages. But we have one advantage which they have not. In Germany there are the Roman Catholic nurses and the Protestant nurses, the Roman Catholic schools and the Protestant schools. In this country all our training-schools are open upon equal terms to both Roman Catholic and Protestant, and no difference or discrimination made. And while the Protestant deaconesses and the Roman Catholic sister nurses make of prime importance the profession of their religion, and the nursing is perhaps for that reason rather a secondary object, in this country the profession of religion finds its most beautiful illustration in the work that they do. Thus the American trained nurse may be said to be more distinctly a member of a profession, for she has given herself to her work as physicians give themselves to the practice of medicine.

It is not by recounting the numerical strength of nurses that we can estimate the position and the development of the profession. That, however, needs more than passing mention, because even if we have 5,000 trained-nurses to-day we have in this country 120,000 physicians, which means only one nurse to every twenty-four physicians, or to every 15,000 of population. So the market is not already overstocked, even if trained nurses to-day are not all employed. It is very true that there were several hundred in Boston last winter unemployed. But think of the hundreds and hundreds of people who needed nurses! The fault lies in not bringing the workers to the work, and that fault rests primarily upon the medical profession, because nurses in the main await the call of physicians, and only when the medical profession understands more fully than it does to-day, how much the success of the medical profession depends on nurses, may we look forward to the bringing into the work all the nurses who are willing to work.

In trying to set before you the present condition of the nursing profession I want to picture what the nursing profession stands ready to do to-day. What as physicians may we expect nurses to do? Well, we certainly may expect this, that all our surgical material of every sort shall be kept in perfect order and in perfect aseptic condition by the trained nurses of to-day. This work demands a high degree of intelligence, considerable skill and a professional conscientiousness that only the trained nurse stands ready to give. Again, physicians may properly expect of the trained nurse of to-day that the patient about to be operated upon shall be put in perfect condition for the operation, and that the room in which the operation is to be done shall be put in complete readiness. Moreover, he may expect that after he leaves the sick-chamber the patient shall be taken care of so scrupulously that all his directions shall be minutely carried out, and that a record shall be sent to him perfect in its details, in its accuracy, and as often as he may require. In his poor practice he has the right to expect of the nurse of to-day that she shall go to the sick-room that is so filthy and forlorn that his visits seem a mockery, and shall clean that house, and bring order out of chaos. In midwifery work he has a right to expect that the trained nurse shall watch the case from the beginning of labor, send him records of its advancement, and be fully able to carry it out and do everything for the mother and child provided the case be a perfectly normal one. Now in these particulars, and they are only a few which I select here and there, the physician has a right to expect full and satisfactory service, and the trained nurse stands ready to give that service.

Now, the question comes, How is the physician to get it? The answer requires more than a passing thought. Nurses are ready to work and would be willing to work for nothing while waiting for other cases, as young physicians are glad to work for nothing while waiting for more lucrative practice. But the nurses are not in touch with the medical profession. The two professions are not estranged, because they have never been in complete harmony; and physicians must go more than half-way in securing that co-operation which will be beneficial to both professions. Just think of the disadvantage that the nurse labors under in the mere matter of registry. What if we physicians were obliged to submit to rating at the hands of nurses. Suppose we found employment only as we were called out from some central registry in the hands of a committee of nurses, where were kept the reports, which we might never have the liberty of seeing, sent in by disgruntled patients. Now that is where the nurse stands to-day. She finds employment only at the pleasure of a registry which intends to perform its duty first for the benefit of the public, and secondly of the medical profession, and lastly for the benefit of the nurses. We know very well that patients are sometimes very unreasonable, and that their complaints sometimes have very little foundation. Sometimes when nurses have tired themselves out in conscientious self-sacrifice the only thanks they get from the patients they nurse are growls and grumbles. It is unfair to the nursing profession that such complaints should be put on record without the nurses being free to defend themselves or to profit by just criticisms. This difficulty in registration in part accounts for the fact that trained nurses are not now in more general employment. Even if they want to work for nothing, they are not sure of finding suitable opportunity from the registry. They do here in Boston volunteer for gratuitous work. Under the guidance of different clergymen in the city some nurses devote several weeks each year to purely gratuitous service, and many nurses of my acquaintance would be very thankful indeed to give more service under the leadership of the medical profession if they could be at the same time learning.

And this brings us to the very touchstone of the question. The modern trained nurse is willing to do anything provided she can learn to be a better nurse by doing it. It is not generally recognized that the modern trained nurse is a professional person, guided and governed as members of the medical profession are guided and governed. She is willing to work at anything provided she can be a better nurse for that work. Of course, she is not willing to go and do absolute drudgery where there is no opportunity for earning her bread, and no opportunity for learning anything; and unless the medical profession steps forward and helps to arrange matters so that nurses shall find that opportunity for continued instruction, we have no reason to grumble if the nurses stand back and wait for lucrative cases.

There is another reason that interferes with their working. There is a popular feeling that nurses are

paid too much; and that is held to be the case by physicians who perhaps charge three or five dollars a visit, amounting to twenty or forty dollars for the week's charge. They may not have been in the sick-chamber each day more than a half-hour; but if the nurse who is there during the day and night should charge as much, it would be considered an extortion. The trained nurse comes into competition with the old untrained nurse, who was willing to go out for ten or fifteen dollars a week and was well paid. But the trained nurse can do a great deal more and is not so well paid even if paid twice as much.

Another objection to the more extended employment of the trained nurse, is the notion that she is inclined to take charge of the case, and that it is better not to tell her too much or take any steps toward extending her education lest she usurp the physician's place. That view is totally wrong because the more the nurse knows the less likely she is to usurp the responsibility of the physician. The old-time nurse was always willing to do this. She never hesitated in giving a diagnosis. I remember an old-timer taking care of a patient of mine when I was considerably in doubt as to the diagnosis, who did not seem to be the least in doubt; and while I in my ignorance did not even think of the patient's liver, she declared that the patient's "liver pin" was out of order. She had probably looked inside of a Connecticut clock, and imagined the inside of the human body was somewhat like it. I remember putting on a breast bandage, and the next day asking the patient if it did her any good. She said she didn't know whether it did or not; the nurse had whipped it off as soon as I left the house, saying that she did not approve of such things. It will be difficult in a few years to believe the stories of the old-time nurses. And now, in this transition stage, it is pretty hard for the trained nurse who is, to begin with, an intelligent woman and well educated, who has given several years to the acquirement of her profession, it is pretty hard that she should be judged and treated in the way that the old-time nurse was.

After picturing what physicians may rightly expect from the trained nurse of to-day, and mentioning the different directions in which she stands ready for service, I must pass to the question, Why cannot any physician here in Boston avail himself of such services? And the answer can best be given by asking why do they have such privileges in other places. I know of many of the smaller cities of Massachusetts, and some of the larger towns, where physicians do have all the advantages I have mentioned, because in those places the physicians have banded together to do on their part something towards the real advancement of the nursing profession. Let a company of physicians agree to give a portion of their time to this work, and they will soon have student nurses who will be most glad to do all these services I have mentioned in return for the instruction that they may so receive. Think for a minute of the little community down in Virginia at Hampton where a few white people, a few educated people, are surrounded by a large population of densely ignorant negroes. The former suffering and the ignorance in that district is something dreadful to think of. But within the last few years a training-school has been established down there, and now the physicians practising in Hampton can call upon student nurses to go to any sort of case. They can send out a couple or squad of them to any part of that country where they find wretchedness, where a few years ago they would turn round in despair and not make a second visit because their efforts would so evidently be unavailing. It is not only in Hampton. In Waltham we have the same advantages. There are a large body of nurses at the beck and disposal of any physician who is willing to join in giving these nurses instruction. The telephone or mail or messenger sent to the training-school will bring immediately a young nurse and an older one as teacher who will go into the house, clean it up, clean the patient up, watch the patient if she be in labor, send a bulletin to the doctor of the advance, clear things up after his visit and go the next day to take care of the mother and baby, sending back a report to the physician so that when the physician comes to his office in the morning he can decide in what direction to drive for his first call. Where families can pay for such service they do pay a little. If a patient needs massage, or a sponge bath, or to have the afternoon temperature taken, all that is done by the nurses. It seems to us there in practice that doctors who attempt the practice of medicine and surgery and midwifery without these advantages are much to be pitied; and when we think of what little we have to do in return for what we get, it seems a small contribution that we have the privilege of making towards the advancement of the nursing profession. It means for each of us perhaps one lecture a week through the year. These students come back to the school every day in the year. They go out to do their work, report to the doctors, receive the doctors' criticisms, and come in for lectures where they are told beforehand what to expect.

Now it seems to me that this fundamental idea must be grasped, that it is just as unfair for us to expect nurses to acquire knowledge only by experience as it would now be unfair to expect the medical profession to return to the old way of studying under the wing of physicians in private practice and learning how to do things only by seeing them done. The medical profession has advanced so far that that seems perfect folly. We cannot understand how the old physician could have learned enough to begin his practice simply by watching the practice of another. It is now incorporated in our notion of what is meant by medical education that a student of medicine shall be told beforehand what to expect and how to treat conditions he will find. It is so with the nursing profession. It is derogatory to intelligent womanhood, unjust to a rising profession, to expect that nurses shall learn only as they see work done. Of course, the profession of nursing, like the profession of medicine, is both a science and an art, and of course an art can be learned not from text-books nor from lectures, but only from personal observation. You cannot learn the touch of a kind physician from any page nor from any lecture. You must see the physician in active practice, see a master of the art of medicine in the wards of a hospital, at least, and it is to your advantage if you can see such practice in the private family also, if you would acquire the art.

So nurses must in the main learn the art of nursing from other nurses. There has been from the foundation in Kaiserwerth a direct succession. It was what Theodor Fliedner gathered in all parts of the world, and what Florence Nightingale in her turn was able to impart to her pupils and her pupils to others, that

constitutes the art of nursing; but besides that, there is an immense amount of knowledge that the student nurse can get from text-books and lectures, and that she must get before she meets the cases where that information is desirable. It is just as easy to teach a nurse, for instance, how to nurse a case of typhoid fever before she meets a case as it is to teach a physician how to treat the disease before he sees it. It is even easier, because the physician besides being taught to treat typhoid fever must also be taught in lecture how to recognize it. The nurse is saved that. It is not her business to make the diagnosis, but to carry out the treatment ordered. And I would just as lief have a nurse who had never seen typhoid fever, but who had been thoroughly trained as to the treatment required, as a nurse who had learned how to take care of typhoid-fever patients only by observation, for the typhoid cases where she learned her lessons would not very likely be like the case of typhoid fever where I wanted her. So with ever so much of the work that nurses have to do, much can be taught in lecture and can be studied from books.

Ten years ago I remember asking a bookseller in Boston to send me all the books on nursing that were to be found; and I think I am within the limits when I say that the whole library amounted to not over a dozen books. Now, books come out every month. There were then no periodicals of any kind devoted to nursing, and no mention in the medical periodicals about the art of nursing. Now, there are several such journals; and in a great many different ways, in congresses of nurses, in graduate-nurses associations, in training-school clubs, in the American Association of Superintendents of Training-Schools, and notably in the Section upon Nursing at the World's Fair, where the famous nurses from all parts of the world and likewise physicians interested in the problem were present and read papers, much has been done and is being done to advance the profession of nursing.

My main purpose to-night is to show how any physician can do something towards this advancement, and how richly he will be repaid by such exertion. Of course, here in Boston there are large training-schools in successful operation, and Boston used to be a centre for America. Training-schools, as they were started in different parts of the country, sent here for their superintendents; but Boston has now fallen behind in comparison with the advance made in New York and Baltimore. One reason for this drifting backwards can be very plainly seen in the self-satisfaction each school has in its own methods and in the rigid exclusion that is maintained. A visiting superintendent would not be allowed in a Boston training-school to even see the methods of training employed; while in Baltimore and in New York a visiting nurse is received at the training-schools with as much courtesy as a foreign surgeon would receive in Boston. The visiting nurse is made at once the guest of the institution and afforded every facility of studying the methods employed, and as a result of such proper professional cooperation there is a general stimulation of interest. If one school has an advantage, it is immediately shared. The nurses of the different schools meet together, the superintendents are close friends, and carry into good effect the different ideas as they are developed, and the profession advances rapidly. Unless there is some interchange of thought, some interchange of new-found theories and methods, of course the different schools, while they may progress, will progress only in the way that China does. But after all, Boston is Boston, and it would be the height of presumption to point out any possible improvement in the Boston training-schools. But when we look abroad through the country as a whole, and at the new training-schools as they are being established, we find not only great encouragement, but we can see splendid opportunities there for the active co-operation of any physicians who are interested in the movement. These schools welcome the volunteer services of physicians who are willing to give instruction either in the schools or outside of the schools, and it is only where outside instruction is made a part of the curriculum that real advance may be expected. It is all well enough to train a nurse to do the work of a hospital while inside the hospital buildings, of course she can only there be so trained; and it is equally evident that she cannot in any hospital ward be well trained for private work. Work for a medical man, as each soon learns, is different outside of the hospital from what it is inside; and it is ten times more different for the nurse.

This is no new idea. It is only within the last ten years that any training was given in this country outside the hospital walls. But in 1859 there was a school established in Lausanne where there is not even yet a hospital; and the graduates of that school, five hundred in number, are to be found in different parts of the world, not only in private practice, but many of them as heads of hospital work and superintendents of training-schools. The work of training nurses is entirely carried on outside. In the morning they have a lecture upon the work of the previous day, and upon the work already before them. One or two nurses are sent out to this kind of nursing, another pair to another kind of nursing, and so on. When they come back with their reports they are criticised, and during their day's service they are visited by the medical men in charge or the superintendent or assistant superintendent. At the end of a certain course of day-work they are sent out to do similar night-work, and visited to see if they do their work correctly. They are taught what to do in taking care of private patients so well that when they get through their three years' course they stand among the very best of the educated nurses of the present day. So it is no new idea, and although not favored in Boston is rapidly becoming so elsewhere. In the Long Island Hospital Training-school, for instance, if a surgeon or a physician of the staff there has a private patient that he is anxious about, he sends not to the registry to get a nurse of whom he knows nothing, but to the superintendent of nurses, who will send to him a student nurse accustomed to his methods. This is better both for the surgeon and for the nurse. And, it is in this line that the work of training nurses will develop. Nurses from the training-schools will be sent out during part of the course to private work under the physicians who are giving them instruction. In that way the physicians will have splendid service even in the families of the poor. There is a complete interchange of values. The nurse has her time to give in return for her education. Her time is of value to the sick patient and to the physician. The physician has time to give instruction to his class of nurses, because that takes less time than without their aid he would have to give to the nursing details of patients where there is no nurse. Nobody gives any money; the nurse gives her time;

the doctor gives his time and there results a complete care of a patient in place of the very incomplete care she would otherwise receive. I do not think any one who is acquainted with what an intelligent student nurse can do if he had to choose for himself between the few minutes' visit of a physician and the twenty-four-hour care of a day or night nurse would hesitate in deciding which he would have. The medical service or the surgical service is not made of less importance by emphasizing the importance of the nurse.

When we consider this problem we must keep in mind that the nurses are to the physician what the staff is to the general. The chief of the staff does not stand ready to take the general's place in case of the general's death on the battle-field. The general's place will be supplied by the senior officer of the line, and the staff-officer will go on serving him just as faithfully and truly; but what the staff stands ready to do is to carry out in fullest detail the orders and the wishes and the least hints given by the general in command. So with the executive officers of the ship. The captain is not undervalued as the executive department of the ship becomes more skilled. What if the executive officer on board is able to do every little thing, the function of the captain is not thereby lessened. The physician's service is not less great, the surgeon's service is not less valuable, when surrounded by a corps of trained nurses willing and glad to do his least bidding, nor need it be feared that the medical profession will ever lose its great advantage. The more completely the orders and the directions and the wishes of the medical profession can be carried out, the more good the medical profession can do. And I really believe that were it fully in evidence before us how many good intentions and even how many orders of the physician and the surgeon, miscarry simply because of lack of faithfulness in the execution of the orders, I believe the importance of the nursing profession would become so prominent that there could not be any hanging-back about it; there would be only an intense conviction on the part of physicians and surgeons everywhere that we must take hold of the problem if we are to do our part.

Now the trained nurse stands even here in Boston asking for help. There is a graduate nurses' association asking for lectures and for chances to work where they can learn improved methods of treatment. And I hope wherever it will be your privilege in the future to do so that you will throw your influence in the direction of advancing the nursing profession. I not only plead for that as a matter of evident self-interest, but I plead for that action on your part as a matter of simple justice. If a physician dies in the diphtheria wards of a hospital all the papers laud his memory. And popular sympathy goes out for the poor tired doctor who does this and does that, but how little is ever said of the nurse who not only goes into the wards of contagion, but stays there; who not only fearlessly meets the danger that the doctor meets when he goes in for a few minutes and out again into the fresh air, but who holds the little, dying, diphtheria child in her lap while it takes its last breath, not because she wants to, but because the little thing clings to her heart. Little is said of the devotion that tires not even by long days and night after night, until she, in comparison with the doctor's service, earns a veritable halo. Think of the nurses who work so tirelessly, so conscientiously carrying out the doctor's orders and struggling even to the very end. If we are depressed with the loss of a patient we have seen half an hour for a few times a week, think of the depression of the nurse who has lived there and felt the cling and clutch of the dying soul hanging on to life. As a matter of simple justice to intelligent educated women who are giving their whole lives in noble devotion, I plead for a larger interest in their work on the part of the medical profession, and I plead for a constant readiness on the part of every member of the medical profession to do every thing that in him lies for the advancement of our sister profession of nursing.

### METAPNEUMONIC EMPYEMA.[1]

BY CHARLES F. WITHINGTON, M.D.,
*Assistant Visiting Physician, Boston City Hospital; Instructor in Clinical Medicine, Harvard Medical School.*

It has long been recognized that pleurisy as a secondary affection stands in an intimate relation to many infectious diseases. It is often found in scarlet fever, variola, typhoid fever and rheumatism. It complicates traumata, sub-diaphragmatic abscesses, peritonitis and pelvic inflammations, especially those related to puerperal infection. The general infectious influence belonging to these conditions is reinforced in the case of tuberculosis, pneumonia and pulmonary cancer by the element of contiguity, with the natural result that tubercular and pneumonic pleurisies are especially common. No constancy in the character of the pleuritic effusion, as to whether purulent or serous, exists with regard to any of these infections. The generally reported frequency of empyema in connection with scarlet fever is perhaps explainable from the fact that children's pleurisies are more apt to be purulent than those of the adult, and that most cases of scarlet fever are in children.

The general ratio of empyemata to all pleurisies is variously given as from 14 to 20 per cent. What proportion of metapneumonic pleurisies are purulent I am unable to say. Though the complication is by no means rare, it seems to me sufficiently important to warrant attention, especially as in so important a discussion as that of the New York State Medical Association,[2] the first speaker only refers to croupous pneumonia as "perhaps" one of the causes of empyema. On the other hand, Ewald [3] finds that no less than 36 per cent. of the cases of empyema which he collected from the Charité Hospital in Berlin were of pneumonic origin. I therefore ask attention to the following cases:

Case I. W. D., male, age nineteen. Good family history. Never seriously ill before.

April 22d, taken suddenly with chill and some pain in chest. Two days later, April 24th, admitted to hospital. In right axilla and at base behind, diminished respiratory movement; dulness; increased voice sounds and tactile fremitus; crepitant râles.

April 27th. Fifth day of disease. Signs of consolidation intense at right base; friction râles on left side. Defervescence occurred on the eighth day of the disease, but dyspnea continued, with much pain and restlessness.

[1] Read before the Boston Society for Medical Improvement, October 22, 1894.
[2] Transactions, 1893, vol. x, p. 84.
[3] Charité Annalen, 1874.

May 2d. Eleventh day. Flatness at bases. On right side signs of resolution over middle lobe, and of fluid at base. At left base fine moist râles, friction rubs and signs of probable fluid. This condition continued without improvement for the next few days. Dyspnea marked.

May 4th, a considerable increase in the cardiac area was made out. The left edge below was indistinguishable from the flatness of the left axilla, but the right side extended to the parasternal line, and a marked increase in the dulness over the base of the heart was evident.

May 8th. Dyspnea much increased. Sixteenth day of illness. Fluid at mid-scapula on right. Aspirated in tenth interspace, and 28 ounces of odorless pus was withdrawn with considerable relief.

May 9th, a marked increase in the cardiac area was demonstrated, the upper limit being one and a half inch below the sternal notch, the right one and a half inch to right of sternum at level of nipple, and the left edge two and a half inches outside the left nipple. This was believed to indicate a pericardial effusion; but as there was also evidence of fluid in the left pleura, aspiration was performed on this side in the ninth space to determine the character of the fluid. It proved to be serum. Ten ounces was withdrawn. It was quite clear, except at the end when it was slightly opaque and reddish. There was no pus. Very unfortunately neither the pus from the right nor the serum from the left side was submitted for bacteriological examination.

The removal of this small amount of fluid seemed to produce a slight return of the heart toward the left side, but there was still a marked dulness to the right of the sternum in the fourth intercostal space. Whether this dulness also occupied the fifth space to the right of the sternum (Dr. Rotch's test of a pericardial effusion) could not be determined on account of the considerable amount of fluid still remaining in the right pleura. No attempt was made to aspirate the pericardium, but the patient was transferred to the surgical side for permanent opening of the empyema. This was done on May 12th, the twentieth day of illness, but he survived the operation only three or four hours. No autopsy was allowed. A report was made by the bacteriologist of a culture from the pus obtained by operation, that it represented a pure culture of the staphylococcus pyogenes citreus.

CASE II. M. S., female, married, age forty-five. Family history good, and previous health fair except fistula five years ago. Taken suddenly ill August 13th, while sitting at the window, with sharp pain in left costal region and much dyspnea; slight dry cough, without expectoration. Admitted August 16th, on fourth day of illness. Well-marked signs of consolidation over left lower lobe, the dulness becoming absolute at extreme base. These signs continued without much change till August 21st, when an increase of pain was complained of and flatness was observed through the left back below the angle of the scapula and in the axilla. The heart was displaced to the right, the apex being two inches to the right of the nipple. Respiration and voice sounds diminished. Aspirator needle introduced in posterior axillary line, at eighth interspace and 34 ounces of foul-smelling pus removed. The first flow of the fluid was thin and purulent, but later it became thick pus with some blood at the very end. The next day some resonance was observed as low as the seat of puncture, and the apex of the heart had returned three-quarters of an inch toward the left.

The report of the pathological laboratory on the bacteriological examination was as follows: "Culture tube contained many fine, pin-point colonies and a number of large, light-yellow, shiny, round colonies. Former are diplococci without chains; latter are short oval bacilli. Diagnosis: pneumococcus and bacillus coli communis present in pus. Cover-slip showed many leucocytes but no organisms."

August 24th, the level of flatness had risen to one inch above point of puncture, and the patient's condition was weaker and the pulse poor. Despite these unfavorable symptoms she was transferred to the surgical service for operation. The eighth rib was excised, and a pint of very foul pus evacuated. She failed, however, and died two days after the operation. No autopsy.

CASE III. P. W., female, age twenty-six. Father died of phthisis, but patient is strong and robust. Nine months ago had diphtheria with good recovery.

August 16th, visited a harbor resort and danced all the afternoon. Returning, sat in an exposed position at the bow of the boat, without a wrap, and felt cold draught on her left shoulder.

August 18th, went to bed with a chill, and woke at 2 A. M. the same night, vomiting. Cough with bloody expectoration followed.

Admitted to hospital August 20th. Marked signs of consolidation in left lower lobe, except at extreme base where there was flatness, and where the strong tubular breathing, increased voice sounds and tactile fremitus of the upper part of the lobe were absent.

August 23d. Effusion had risen to the angle of the scapula, consolidation persisting above.

August 25th. Effusion just above angle of scapula, consolidation still remaining above. Heart not materially displaced.

During the following week, the second of the illness, the effusion gradually increased, with harsh respiration and moist râles over the upper lobe. The heart was not displaced but a systolic mitral murmur had developed. The pain had increased and on September 1st she was aspirated in the eighth interspace in the post-axillary line and eight to ten ounces of pus were withdrawn. This specimen became contaminated, so that the bacteriological cultures were not reliable.

Two days later, a permanent opening being deemed desirable, Dr. Gavin kindly operated in my ward to spare the patient the shock of removal. An incision was made in the axilla in the seventh interspace, but to our surprise failed to reach pus; and an exploratory puncture made near the site of the former one also gave a negative result. The wound of the operation healed kindly in about twelve days and the patient was meantime comfortable.

September 6th, an examination of the sputa was made by the pathologist who reported: "Some diplococci seen, with at times a suspicion of a capsule about them, but no clearly defined capsule. No bacilli tuberculosis found."

September 19th, the patient began to cough for the first time in many days and to expectorate freely. The signs of effusion still persisting, she was again aspirated near the site of the original puncture and about three ounces of thick, odorless pus were re-

moved, which gave, according to the pathologist's report, "a pure growth of the pneumococcus."

September 26th, the healed incision of the surgeon's operation of September 3d reopened and discharged a considerable quantity of pus. This discharge was facilitated by the introduction of a drainage-tube, which remained in for eight days. At the present time the cavity is discharging freely, and she is out and about and gaining steadily.

Case IV. J. M., female, age fifty-three, widow. Anemic; poorly nourished. Says she has been well except for rheumatism.

May 13th. Sudden onset of illness, with pain and bloody sputum. Entered on fourth day of disease. Pneumonic consolidation of left lower lobe was diagnosticated. The temperature fell by lysis reaching the normal on the ninth day; but she had involuntary dejections, and gradually failed, dying on the eleventh day. No fluid was detected during life.

Autopsy showed in addition to the pneumonia of the left lower lobe an empyema of the same side, with nine ounces of dirty-yellow purulent fluid. This patient was also found to have gummata of the liver and syphilitic disease of both lungs.

The bacteriological examination specimens from the lung and pleural exudate, gave on blood serum pure cultures of the pneumococcus.

The four cases already reported occurred in my own service at the City Hospital during the past summer. I present only one temperature chart, that of Case I, which is a perfectly typical representation of this combination of diseases, showing the defervescence from the pneumonia on the eighth day, with subsequent rise due to the pleuritic involvement. It is noteworthy that we have here simultaneously a purulent pleurisy on the right side and a serous one on the left.[4] There was also an undoubted pericardial effusion, but as to its character we remain in the dark. To the point of the diverse nature of the two effusions, both of which would seem to own the pneumonic infection as their common origin, we will return later.

I will now very briefly outline the chief clinical features of a few other cases of distinctly metapneumonic empyema, greatly condensed from the hospital records, of the past ten years. They represent by no means all the cases which have occurred during that time.

Case V. Male, age forty-one. Taken sick April 24th with pneumonia. May 15th, by aspiration, one quart of pus was removed; May 19th, 45 ounces; May 26th, 46 ounces. May 29th, permanent opening. July 25th, died.

Case VI. Female, nurse. January 1st, had diphtheria. April 20th, same year, had measles; discharged, convalescent, May 3d. May 6th, broncho-pneumonia; May 20th, convalescent, but slow gain in strength. June 24th, aspirated, and pus obtained. June 28th, pus again obtained. July 10th, permanent opening. July 28th, died. No autopsy.

Case VII. Female, age thirty-two. March 18th, chill, followed by pneumonic signs. April 2d, rise of temperature; effusion diagnosticated. May 8th, aspirated; twenty-five ounces laudable pus. May 24th, aspirated; twenty-eight ounces laudable pus. This was followed by improvement, and patient was walking about. July 18th, aspirated; thirty-two ounces sweet pus. July 25th, discharged to surgical side for operation. October 3d, left hospital with wound of permanent opening nearly closed.

Case VIII. Male, age seventy-two. April 20th, chill; cough, with rusty sputa. April 30th, cough had stopped and patient was convalescent, but great prostration and dyspnea. May 7th, signs of effusion. May 25th, pus removed by aspirator, and again on June 8th. The next day, June 9th, died suddenly.

Case IX. Male, age thirty-five. Cough began with brownish sputa about November 23d. Kept about till December 20th; then had a chill. Signs of effusion. Aspirated on entrance, December 22d; very little pus. Signs of effusion continued. Died December 30th.

Case X. Female, age thirty. December 30th, taken suddenly sick with chill. December 31st, admitted with signs of pneumonia at right apex; good resonance below. January 10th (twelfth day), temperature normal. The next day signs of effusion in right base. January 15th, aspirated two to three ounces of pus. Next day permanent opening; 42 ounces pus evacuated. February 27th, discharged, well.

Case XI. Male, age sixteen. Taken sick August 23d. Admitted September 1st. Roseola, tympanites (typhoid), dulness right lower back. September 4th, increased voice sounds and fremitus, with crepitant râles. Pneumonia diagnosticated. September 8th, effusion appeared. September 16th, aspirated 38 ounces of pus. September 20th, aspirated 24 ounces of pus. September 23d, permanent opening. November 20th, discharged, well.

Case XII. Male, age thirty. March 16th, sudden onset of illness with chill; pneumonia evident in left lower back and no signs of effusion. March 26th, crisis on tenth day. April 3d, pus obtained by aspirating, also, April 10th. Operation the same day. Discharged May 12th, relieved.

Case XIII. Male, age twenty-one. Onset January 23d. Consolidation right middle and lower lobe. February 3d, crisis on tenth day. February 9th, effusion recognized, which rapidly increased. February 10th, aspiration of pus; permanent opening. March 21st, discharged, well.

The foregoing cases have been presented entirely from the clinical standpoint, and the bacteriological evidence is unfortunately largely wanting. But the important question as to all such cases is, What is the relation of these empyemas to the specific micro-organism of pneumonia? In the majority of such cases as have been studied, this question is answered by the finding of Fränkel's diplococcus in both the sputum and the purulent exudate, and post-mortem in cultures from both the lung and the pleura.

But why do we find in a majority of cases of pleuropneumonia only a serous exudate, and why can we have, as in Case I, a serous exudate in one pleura and a purulent one in the other, when both come from one presumably identical primary infection?

In answering these questions we can say, first, that the difference between a serous and a purulent exudation is probably more apparent than real. It is a well-known fact that serous exudates become purulent, not usually, as was once thought to be the case, by infection through careless paracentesis, but through a natural evolution. Hence though not all serous effusions

[4] A precisely similar case reported by Ewald (loc. cit., Case xxxii) is the only other one of the kind that I have come across.

become purulent, many purulent ones have once been serous, and have gradually undergone an increase of cellular elements till they have become converted into pus.[6] This accounts for the rarity with which pus is found in the early days of an infection, two of Ewald's cases in which it was detected on the fifth and seventh days respectively, being regarded by him as quite exceptional. The occurrence, outside of these cases, of genuine primary empyemata is, of course, not denied.

Further, it is known that certain micro-organisms which are generally characteristic of pus may exist in a primary serous effusion without ever forming pus. For example, Goldscheider[6] has found (and his conclusions are in accord with those of other observers, as Levy, Weichselbaum, etc.), cases of primary pleurisy in which the streptococcus and others in which the staphylococcus pyogenes existed, which never developed pus but which underwent complete and permanent resolution.

It has been shown that the production of pus is dependent not alone on the specific character of the pus organism but on other conditions favorable to its growth connected either with the coccus itself or with the organism which receives it. Perhaps one such condition has to do with the numerical quantity of the micro-organisms. Thus Hermann at the Pasteur Institute found that at least 500,000,000 staphylococci were necessary to produce an abscess subcutaneously in a rabbit, and that different tissues of the animal possessed a varying susceptibility. Whether the fact be due to a less quantity or a less virulence of the streptococcus in certain cases, it is at all events true that that micro-organism which often leads to empyema may produce only a serous effusion. It seems, therefore, probable that the pneumococcus whose frequent causal relation to pneumonia and its accompanying pleurisies is demonstrated may, according to varying conditions, produce now a simple pneumonia of less or greater severity, now pleurisy with merely a serous exudate, and now one in which the serum passes over into pus.

Double empyema, though rather a rare affection, illustrates well the causal relation of pneumonia. Dr. G. A. Sutherland[7] has very recently collected 21 cases of bilateral empyema in children and adolescents. In 14, or 67 per cent., the affection was secondary to lobar pneumonia, and while this ratio corresponds very nearly to that given by Adams for unilateral empyemata in children (when in 32 cases 71 per cent. were metapneumonic) it is especially interesting to observe that in Dr. Sutherland's cases, the double empyema followed in eight of the fourteen young patients a *bilateral* pneumonia.

The presence of the pneumococcus in a pleuritic exudation, while it indicates, of course, that the individual has received the specific infection which is the ordinary cause of pneumonia, does not necessarily imply that the clinical disease pneumonia, that is, a consolidation of the lungs, is present. For several cases were recently reported by Drs. Washbourn and Hale White before the Royal Medical and Chirurgical Society[8] of purulent pleuritic exudate, containing pneumococci, accompanied by fever and serious symptoms, but without consolidation. Of seven cases claimed to be such, one cannot help feeling that in some a latent or central pneumonia may have existed without giving physical signs. But in two cases death occurred after a few days' illness and in each the autopsy showed empyema containing pneumococci, and no involvement of the lung.

Not only may we have a pneumococcus empyema without pneumonia, but, rarely, also a pneumonic pleurisy without pneumococcus. From Levy's report on his bacteriological studies of 54 cases of pleurisy,[9] it appears that among them were 19 which occurred as complications of pneumonia and influenza. Of these ten were serous and nine purulent. Of the former class, three showed no organisms, one the staphylococcus albus, one the same with the pneumococcus, and *six* (five?) the pneumococcus alone. But all nine of the purulent cases contained the pneumococcus.

It is not then to be denied that metapneumonic empyemata may contain other organisms than the pneumococcus — may even contain exclusively the streptococcus or the staphylococcus. This is accounted for by Fränkel and others on the ground that the last-named organisms are secondary growths in the pneumonic lung and yet may be the only ones to penetrate to the pleura. Thus, while Fränkel[10] attaches no diagnostic value to them, either in primary or secondary empyema, he believes that the exclusive presence of the pneumococcus in an exudate shows that the empyema is the sequel of a genuine fibrinous pneumonia; and, further, that the spontaneous healing of empyemata occurs, as a rule, only where this is the organism present. This view of the relatively favorable prognosis in a pneumococcus empyema is in accord with the general opinion of others.

An interesting case reported by Bureau[11] illustrates how a case went on very favorably under the purely pneumococcus infection, but went badly when this became mixed with another purulent organism. The essential facts are these: A woman, age thirty-six, was taken ill on October 23d. There was well-marked pneumonic consolidation of the right base, and a mitral systolic murmur was heard. Examination of the sputum showed the pneumococcus as the only pathogenic organism. Convalescent on the thirteenth day. On the twentieth day there was a rise of temperature with pneumonia of the left lung. Pneumococci again found in the sputum, and after a few days, *in addition*, staphylococcus albus and leptothrix. Purpura developed, and also an empyema. In the pus aspirated there were at first only pneumococci, and later staphylococci — the same change that was observed in the sputum. Death occurred on the forty-fourth day. The autopsy showed an infectious endocarditis, with diplococci in the heart, pleura and peritoneum. The original (right) pneumonia had healed completely.

According to Netter[12] the pneumococcus is the causative organism in 43 per cent. of purulent pleurisies. The remaining 60 per cent. or so are described by him as due to streptococci; but if, as we have seen, a few truly metapneumonic cases present these other cocci, it would appear that pneumonia was responsible for nearly half the cases of empyema, a larger proportion than most other observers admit.

As to the relative benignancy of the purely pneumo-

[6] Wilson Fox (Treatise on Diseases of the Lungs and Pleura, p. 965, American edition) almost alone of recent writers seems to doubt that serous effusions may become purulent independently of outside septic influences, "superadded causes," as he calls them.

coccus empyemata, Netter also speaks hopefully. He has seen four cases which recovered after a single aspiration and has collected thirty-two similar cases from other sources. Whether some of these favorable results, however, did not occur in children, does not appear.

In conclusion, I would make the following suggestions:

(1) In all pneumonias where dyspnea or weakness follows the crisis, watch for effusion, and if found, aspirate for purposes of diagnosis.

(2) If the pneumococcus alone is found in the exudate, consider the pleurisy not a complication but only a phase of the pneumonic process.

(3) Give a comparatively good prognosis to such cases where pleurotomy is called for.

(4) Before resorting to this operation, wait longer than would be justified under other conditions, as there is a slight chance that simple aspiration may suffice.

## DEFERRED DIAGNOSIS.

BY O. F. McCALLUM, M.D., MAITLAND, NOVA SCOTIA.

PHYSICIANS in early practice will sometimes find that after the most careful and prolonged examination of some cases, they will be in doubt as to the right diagnosis. In such cases they should endeavor to carry the diagnosis as far as possible, and explain to the patient the reason for their hesitation and doubt. This is a procedure which every practitioner now and again adopts. In some cases the facts are not sufficient to warrant a conclusion; in others, although sufficient facts are in reality present, yet their observation is attended with so much difficulty, or the case is so complex, that it is desirable, before committing one's self to a final opinion, to examine the patient again and again, and to take time to think over the case. This is truly a scientific method of procedure, which every one, who wishes to arrive at the best possible conclusion must frequently adopt. On first entering practice one will, of course, be frequently in doubt, and until one has thoroughly acquired the confidence of patients, one may feel some difficulty in telling them, when they ask for your opinion, as they usually will do, that he is unable to form a positive opinion as to the nature of the case; for one naturally will think that they will attribute hesitation and doubt, not to the intrinsic difficulties of the case, but to want of experience and knowledge. And in some cases they would be correct. Tact and ingenuity enable some men to get out of the dilemma, but one will, I think, generally find that the straightforward course is in the end the best. Sensible and intelligent people will seldom be dissatisfied if told that the case is one of difficulty and doubt, and that it is necessary before making up one's mind as to its exact nature, to take time for its consideration and further observation. Once having gained the confidence of patients, and acquired a certain reputation, there is no need to hesitate as to the course to be adopted.

To give an illustration of the kind of case in which it is necessary to defer the exact diagnosis: A patient comes, let us suppose, with symptoms of intra-thoracic pressure. On physical examination it is evident that there is a tumor within the chest. But it is difficult, or may be impossible, to decide at the first interview whether the tumor is an aneurism or solid growth. The evidence may seem to be evenly balanced; and sometimes, though it must be confessed rarely, this is naturally the case. The chances being equal, the practitioner may deliberately choose to run the risk of being wrong, knowing if he happens to be right he will gain more credit from being right than he will gain discredit from being wrong. This is exactly the principle upon which the bone-setter makes his reputation. The public hears of the few successful results. They are widely noised abroad, both by the patient and operator; but the failures — the many gross mistakes and too frequently disastrous results — are forgotten, or make comparatively little impression on the public mind. As a matter of experience, it is found that one thoroughly successful result is quite sufficient to counterbalance a large number of serious errors. Now, suppose that the patient with the intra-thoracic tumor dies, and that the positive diagnosis which has been hazarded is found to be correct. The physician congratulates himself, and is congratulated, over the result. People talk of the wonderful diagnosis which Dr. So-and-So made, apparently without any difficulty where others deferred their diagnosis or would not give a definite opinion, and seemed to hesitate and doubt. Well, another doubtful case presents itself. The same process is adopted; but this time the guess — for it is nothing more — is not correct. The temptation to appear brilliant at the risk of failure where the chances seem equal, and to carry the diagnosis further than the facts of the case warrant, is a strong one; but it should be sternly resisted and suppressed. Like all other temptations, it grows stronger and less easily resisted the more frequently it is allowed to get the upper hand, until finally it becomes a habit.

Now, the object of the physician ought not to be to make a few happy and apparently brilliant hits, mixed up with an equal number — it may and probably will be with a greater number — of mistakes, but to arrive in every case at the best possible conclusion which the facts warrant.

Scientific caution is a quality which cannot be too highly honored; and it cannot be too strongly insisted upon that, in forming a conclusion, it is better to err on the side of caution rather than of rashness. Caution may, however, be carried to an extreme. In the great majority of cases which come before the physician, the facts are quite sufficient to enable a competent man to come to a positive conclusion. When one finds a man constantly or very frequently hesitating to give a positive opinion, one naturally thinks that he is not able to form one, and that he is using cautiousness as a cloak for ignorance and doubt. One does occasionally meet with a shrewd man of the world who is not very strong professionally, who knows by experience when he does commit himself to a positive opinion he is apt to make a mistake, and recognizing that positive errors tell injuriously against him, wraps himself up in the cloak of cautiousness, and tries to make capital out of his reserve, by posing as one who gives careful and well-considered opinions.

---

IT has been computed that the death-rate of the globe is 68 per minute, 97,790 per day, or 35,717,790 per year. The birth-rate is 70 per minute, 100,800 per day, or 36,817,200 per year, reckoning the year to be 365¼ days in length. — *Scientific American.*

## Clinical Department.

### REPORT OF A CASE OF UNILATERAL CYSTIC DEGENERATION OF THE KIDNEY COMPLICATED BY TUBERCULAR PERITONITIS.[1]

BY AUGUSTUS P. CLARKE, A.M., M.D., CAMBRIDGE, MASS.

I WAS called, July 26th, to visit B., aged sixty-five years, a cordwainer by trade. He had been of good physique, and had enjoyed excellent health until about eight years ago, when he began to suffer from the effects of an abscess occurring in the abdominal wall, involving the peritoneal cavity, and presenting itself first in the upper portion of the hypogastric region. He, it appears, was taken to the Boston City Hospital, where he remained eight weeks, and was operated upon. At the time of his discharge from the hospital he regarded himself as entirely cured. He resumed his occupation, and was apparently well until about three years ago, when he began to suffer from gastric disturbance, and was unable to accomplish the work of his trade as easily as heretofore. Three months before I was called he had become much worse, and had been under medical attendance during that period, although he was not confined all the time to his bed.

From the history and account of his symptoms as furnished me, I have no doubt that his case must have been regarded as somewhat obscure. When I made my first visit he was in bed; his heart's action was weak; and there was marked ascites with considerable edema of the lower extremities. He complained much of the dyspnea with which he had for some time been troubled.

I suspected that the patient was suffering from some form of renal trouble, and I did not hesitate to apprise the family upon this point. I was, however, told that the kidneys were not affected, that they had been found by the previous medical attendants through recent examinations of the urine, to be free from disease.

During the early part of my attendance on the case there was some abnormal elevation of temperature; occasionally the patient would have a chilly sensation, though there was no prolonged or well-pronounced chill. Nausea and vomiting of bile were other distressing symptoms. Though the patient was suffering from dyspnea, I did not regard that symptom as sufficient indication to bear out the conclusion that there was any distinct cardiac lesion. By eliminating that possible source of disease, the diagnosis was narrowed down to affections of the kidney, mesentery and peritoneum. If the disease in its inception was confined wholly to the mesentery or to the peritoneum, there would have been more marked indications. The advantages usually afforded by palpation in arriving at a correct diagnosis were negative on account of the large amount of fluid in the abdominal cavity.

Dr. Tuttle made a visit with me on August 16th, and advised against resorting to paracentesis. The heart's action at that time was becoming weaker, so that exploratory incision became out of the question. Though the frequent examination of the urine up to this time had been attended with negative results yet we could not help feeling that there was more or less advanced renal disease.

Saline laxatives, digitalis, pilocarpine in connection with tonics, strychnine, nitro-glycerine and other cardiac stimulants were early resorted to with some apparent temporary beneficial effect.

There was about the face a peculiar expression which indicated that the patient had undergone much general suffering; it did not seem to be due to chronic cancerous or malignant disease. The facies was such as sometimes appears in certain cases of tuberculous disease. There was, however, no cough, no night sweats. As regards the action of the kidneys, the quantity of urine voided per diem was not far from the normal amount.

The patient, as said before, was relieved somewhat by the treatment, but afterwards grew worse, and died August 30th.

An autopsy was performed by Dr. Tuttle and myself some twelve hours after death. On section of the abdomen there was found about two-thirds of a waterpailful of fluid. The peritoneum and mesentery presented a peculiar appearance; being everywhere thickly studded with what appeared to be miliary tubercles. The peritoneum involving the liver was also infiltrated with the tubercular deposits though the liver itself on section was normal. The gall-bladder was unduly distended with its usual liquid contents, otherwise it was normal. The urinary-bladder was much contracted. The prostate gland had undergone chronic enlargement. The heart presented no special abnormal appearance. There were no tubercular deposits found in either lung, and there were no plastic adhesions. There was, nevertheless, considerable fluid in both sides of the chest. The presence of this was, no doubt, a contributing cause of the dyspnea. The right kidney was much enlarged and had undergone *cystic degeneration*. The left kidney was nearly normal. The spleen was normal; so also the stomach. The condition of the kidneys revealed by the autopsy showed why the results of the several examinations of the urine were negative. The left kidney being normal or nearly so the urine secreted by it must also be normal; the right kidney having undergone extensive degenerative changes, and the glomeruli through which the albumin principally escapes having also been destroyed, there could scarcely be expected to occur any real loss or escape of albuminous elements and other products significant of nephritic lesion.

In closing, I would here incidentally remark that it would seem to be important to bear in mind that such particular changes in the kidneys may take place, and that when conducting an examination in the case of any obscure abdominal disease, the existence of such a possible condition should not be left unconsidered.

### A CASE OF SUBCUTANEOUS SUTURE OF A FRACTURED PATELLA.

BY JOHN W. KEEFE, M.D., PROVIDENCE, R. I.,
*Surgeon to Rhode Island and St. Joseph's Hospitals.*

OF the many methods that have been devised for treating fractured patellæ, that by subcutaneous suture, described by Dr. L. A. Stimson, seems to offer the happiest results, with a minimum amount of risk.

The following case is one that came under my observation at St. Joseph's Hospital, this summer: T. A. K., male, twenty-four years old, student. On June 28, 1894, while playing ball, he was tripped by

a small, round stone, and felt something "give way" in the left knee. He did not fall, but deliberately sat down; and after a few minutes he arose, and walked about ten yards. He then felt as if something had again "given way," and was unable to walk. He was taken to his home, and later to the St. Joseph's Hospital. There was considerable swelling, due to a large amount of effusion into the knee-joint, and a transverse fracture of the left patella was found at the junction of its middle and lower thirds. The leg was elevated, and bandaged to an inclined splint with ice bags to the knee. Twelve days afterwards the effusion in the joint had disappeared to a considerable degree, leaving a separation of about a finger's breadth between the fragments.

OPERATION.

The field of operation was rendered aseptic, and the sutures and instruments sterilized by boiling ten minutes in soda solution. The patient was etherized. Four incisions, one-fourth of an inch long, were made through the skin at each corner of the patella. A strong twisted silk suture, similar to those employed in tying the pedicle of an ovarian tumor, was passed through the ligamentum patella, making an entrance at one, and an exit at the other lower opening. The suture was again entered at the lower opening of exit and passed beneath the skin, by the side of the patella, through the upper opening on the same side; then transversely, through quadriceps tendon, along the upper border of the patella, and out through opposite upper opening; then again, through latter opening, beneath the skin and by the side of the patella, through lower first point of entrance; thus encircling the patella. By leaving a loop of the suture at each opening, one is materially aided in making traction when the ligature is tightened. The fragments may be brought together by tenaculi in the hands of an assistant. The suture was drawn tightly, tied, and the ends cut short, the knot being buried in the wound of entrance. The four incisions through the skin, were closed with silkworm-gut sutures. An aseptic dressing was applied, and the leg bandaged to a posterior, inclined splint.

Eight days after the operation the wounds were dressed for the first time and the silkworm-gut sutures removed. Swelling diminished. No evidence of suppuration. An antiseptic dressing and posterior splint. Ten days later a dressing consisting of a light plaster-of-Paris splint was applied, reaching four inches above and below the knee-joint. The plaster splint was removed one month from day of operation. There is at present about forty-five degrees motion in the joint.

Thirty-five days from the date of operation the patient was able to walk without a cane, and to fully extend the leg. The line of fracture can be felt, but no evidence of separation of the fragments. Hot and cold douching, and massage advised. Ordinary bandage about the knee.

August 30th. Elastic knee-cap worn. The range of motion was gradually increasing, and no inconvenience was felt from the silk buried suture.

Nine weeks after the operation the patient was able to flex the leg to 115 degrees.

I should advocate performing the operation as soon as practicable after the injury; aspirating the joint if necessary to enable one to approximate the fragments; but this latter procedure would seldom be found necessary. The advantages of this method of treatment are, that the fractured surfaces are maintained in perfect apposition, thereby favoring bony, rather than fibrous, union; the joint is not opened, thus preventing the possibility of joint infection; the operation is simple and readily performed, and passive motion may be commenced early, rendering even partial ankylosis of the knee-joint improbable.

## Medical Progress.

### RECENT PROGRESS IN OPHTHALMOLOGY.

BY MYLES STANDISH, M.D., OF BOSTON.

(Concluded from No. 26, p. 643, Vol. cxxxi.)

SUBNORMAL ACCOMMODATIVE POWER.

THEOBALD[6] says that, in 1,615 consecutive cases of refraction and muscular anomalies met with in private practice, since his attention was first attracted to this condition, he found subnormal accommodative power, more or less marked in 155 times, or in about nine and a half per cent. of the total number.

Theobald's doctrine of subnormal accommodative power is based upon the observation that, while the normal balance of the lateral muscles of the eyes, as shown by the vertical diplopia test is in distant vision one of orthophoria, in near vision (at the usual reading distance) the normal vision is exophoria, the relative divergence amounting, as a rule, to from three to five degrees. In cases where there is less exophoria than this for near if emmetropia be present, convex glasses for near vision only are indicated. In hypermetropia, stronger glasses for near vision than can be worn for distant vision may be called for; and in myopia weaker glasses must be prescribed for reading than would otherwise be given.

ON THE PRESCRIPTION OF LENSES IN THE PRESENCE OF ANOMALIES OF THE OCULAR MUSCLES.

Savage[7] lays down the following rules which he believes should govern the prescribing of glasses in cases of abnormalities of the ocular muscles:

(1) Give a full correction of hypermetropia when associated with esophoria.

(2) Give no correction, or only a partial correction, of hypermetropia when associated with exophoria.

(3) Give a full correction of myopia when associated with exophoria, and when there is orthophoria.

(4) Give only a partial correction, or none at all, of myopia when associated with esophoria.

DISTURBANCES OF VISION IN HYSTERIA.

Drs. J. K. Mitchell and G. E. De Schweinitz[8] in an article upon this subject, come to conclusions which are briefly as follows:

(1) Achromatopsia, or loss of color sense, is not present in American cases (certainly not as described by French observers).

(2) Reversal of the normal sequences of colors, so that red is the largest field, is usually present when there is anesthesia (although two cases are mentioned of universal anesthesia with no alteration of the visual

[6] Transactions of the American Ophthalmological Society, 1894, p. 138.

[7] Ophthalmic Record, May, 1894, p. 447.

[8] The Journal of Nervous and Mental Diseases, January 1894, p. 48.

fields, and another case in which there was marked contraction but no reversal).

(3) The green field is, relatively at least, more, and more often contracted than the others.

(4) In the difficult distinction between certain types of neurasthenic and hysteric patients, the presence of disturbance of the color sense is of diagnostic import; it is less apt to be present in the former than in the latter, and yet its absence is of little meaning, as it was not found in many cases of hysteria and was found in some neurasthenics.

(5) That it is possible that in rare cases of one-sided or general hyperesthesia that the colors are more acutely appreciated than is normal.

(6) The violence of the hysterical manifestations bears no relation to the disturbance of the color sense.

(7) The following changes in the field of vision are likely to be present in cases of hysteria:

(*a*) Simple contraction of the color fields with unaffected form fields.

(*b*) Contraction of both color and form fields, the green fields being relatively more contracted than the form field.

(*c*) Partial or complete reversal of the normal color fields, most commonly that variety in which the red field is the largest.

(*d*) Unusual obscurations of portions of visual field.

### INCREASE OF TENSION AFTER OPERATION FOR SECONDARY CATARACT.

Teale[9] says that the irido cyclitis or panophthalmitis which sometimes follow this operation has for its initial stage an increase of tension, and if that can be properly dealt with the process will be stopped. He cites two cases of his own in which within forty-eight hours after the operation the patient suffered intense pain and dimness of vision with increase of tension, and recalling advice offered to him many years before in a similar case by Sir William Bowman, he in one case on the third day, and in the other on the fourth day, punctures with a broad needle through the upper part of the cornea and through the iris into the vitreous humor. The needle was turned sideways and allowed a few drops of vitreous humor to escape. In a quarter of an hour, in each case, intense agony was converted into perfect ease and with the most happy ultimate result.

### THE HALO SYMPTOM OF GLAUCOMA.

Richey[10] suggests that the halo symptom of glaucoma must be caused by some condition which is probably to be found in front of the retina, and as the symptom is a prodrome of glaucoma cannot be caused by any increase of tension, and further suggests that the sequence of colors is such as would be produced by the reflection of light from the surfaces of the rhombic prisms of acid sodic urates, or from amorphous granules of the same material, which also has this quality.

M. GUENIOT brought before the Academy of Medicine of Paris two women each of whom had had the operation of Cæsarean section twice performed upon her. The four children were living. The mothers were rachitic, and so were two of the children. In one case there was an interval of seventeen months between the two operations.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

JOHN T. BOWEN, M.D., SECRETARY.

REGULAR Meeting, Monday, October 22, 1894, the President, Dr. C. F. FOLSOM, in the chair.

DR. C. F. WITHINGTON read a paper on

### METAPNEUMONIC EMPYEMA.[1]

DR. A. L. MASON: Cases such as Dr. Withington has reported have been common of late years, and I think especially so during the late epidemic of influenza. What connection the influenza germ may have with these empyemas is not altogether clear; but it has appeared to me that since the influenza epidemic has subsided empyemas have been less frequent, pneumonias also.

The diagnosis of these cases when they come to the hospital is sometimes difficult. They enter late, having suffered from pneumonia perhaps a longer time than is reported; and the physical signs are often obscure, those of pneumonia being present as well as those of effusion. When cases are watched from the outset it is much easier to treat them promptly and efficiently.

There has been a distinction made, chiefly by French writers, between the so-called metapneumonic and parapneumonic pleurisy, chiefly based upon the statement that the effusion in parapneumonic pleurisy, which occurs in the early days of the pneumonia, is serous, whereas the metapneumonic effusion is purulent. This, no doubt, is often true; but from the case which Dr. Withington reported with double effusion, it is quite evident that empyema may originate very early. The fact, however, that an early effusion in pneumonia is most frequently serous I have verified in a considerable number of cases tapped for extreme dyspnea, the effusion being sometimes sanguinolent from the acuteness of the process.

As to the prognosis in the purely metapneumonic empyemas, I should think it was better than the cases that Dr. Withington has reported would lead one to suppose. The mortality, so far as I can recall in the large number of cases that have presented themselves in the last four or five years, has been very moderate indeed, after drainage. I remember one instance of recovery in an adult after simple aspiration. The pus did not reaccumulate. Such a fortunate result is no doubt more frequent in children; and in the City Hospital records there are a number of instances in which they have recovered from this form of empyema after one or two aspirations. That fact, however, would not lead one to defer a more radical operation, because such a result is certainly exceptional.

There are one or two matters in regard to the drainage of chests under these circumstances which are interesting. One relates to the question of etherization. I noticed that Dr. Withington said one of his cases was operated on in bed without removal. Many of these patients are so exhausted, debilitated by prolonged illness, that the resection of ribs should be deferred. Most surgeons to-day think it important to resect ribs in all cases of empyema, but certainly the result in these metapneumonic empyemata is usually favorable without resection of the ribs; that necessitates etherization, in itself a dangerous procedure

[1] See page 5 of the Journal.

when one side of the thorax is full of pus and the other lung perhaps edematous from pressure. I have heard of a number of fatal instances of this kind which seemed to be the direct result of anesthesia; therefore, a rapid evacuation by simple incision without removing the patient from bed, seems to me to be the proper procedure where there is great exhaustion or great oppression in breathing.

DR. E. N. WHITTIER: I think, Mr. President, after the conversation we had over the telephone with reference to the title of this paper, I shall be obliged to admit myself as occupying a peculiar position. I did not think then that the title could be successfully demonstrated in a paper of the ordinary limits; but I am free to admit that the situation is not very different from that so well described by Goldsmith in which he said, "Truth from his lips prevailed with double sway." For, certainly, after listening to Dr. Withington's paper I must admit that he has demonstrated the right to preface the paper with a title which to some may seem somewhat obscure. I cannot quite satisfy myself, however, as to the impropriety of using para instead of meta. If these cases of purulent pleurisy follow after and can be demonstrated, as in so many instances they have been demonstrated, as dependent upon, I do not see why the other prefix may not with more accuracy be applied. The difficulty seems to be in demonstrating the causal relation between the two diseases. A year ago was a dark experience with me in this regard. I saw a number of cases of this purulent pleurisy, which I supposed was a sequence of pneumonia, and not necessarily in the ordinary sense of the word a complication, and which seemed to resist by reason of the severity of the pre-existing disease the best methods of treatment for purulent pleurisy. During my service in the Massachusetts General Hospital, I saw six cases in a state of great exhaustion from pre-existing pneumonic process, with a history such, that there was every reason to believe that the clinical history furnished was accurate, and leaving the patient in such shape that it was impossible to bring out a good result by the most careful treatment for the succeeding empyema. I believe that if it had not been for the extreme degree of surface inflammation, we should not have seen those empyemas, nor such difficulty in the successful application of remedial agents. Under ordinary circumstances pneumonias are not exposed to influences such as have been prevalent in this community for four or five years. I refer to the "influenza" which is, after all, primarily, a disorder of the central nervous apparatus, and which has modified in no small degree the hitherto observed natural order of diseases, notably the pneumonias and the continued fevers — particularly in the direction of a lessened percentage of favorable results. These collections of pus seem to me to deserve more nearly the name of pleural abscess, than empyema, meaning by that a localized process which would be followed by good result with the ordinary means used to evacuate pus, and that the resection of ribs, and the use of the drainage-tube would be found not to be demanded, in anything like the percentage of cases ordinarily called empyema.

DR. H. JACKSON: I felt as I came in to-night that empyema as seen in children should be classified rather differently from the empyema seen in adults. Pleural exudation in children in a pretty large proportion of cases is purulent. The exudation, as I have seen it in children, often comes on gradually without marked constitutional symptoms, often coming on so gradually that there may be a large exudate in the pleural cavity without giving rise to severe dyspnea. In children I have certainly not diagnosticated the pre-existence of a pneumonia. Dr. Withington, in speaking of cases of empyema at the end of his paper, spoke of a large number of them as following pneumonia in children. In adults my experience with empyema has been small; I have notes of only four cases to draw from. Two of them followed a pneumonia, in each case not what we speak of as a typical frank pneumonia, but a pneumonia of a portion of a lobe; one of them a pneumonia following a septic puerperal case that I saw in a dispensary district, and the other a pneumonia where the fever was slight, where only a portion of the lung was affected. In the two other cases, in one there was no history of any pre-existing disease, and the fourth, an examination of the lung and aspiration of the fluid, showed it to be tubercular. There were signs of consolidation in the lung. The puerperal case had pneumonia of a violent type and empyema, and proved fatal.

As to the organisms found in empyema, Prudden gives a list of twenty-four cases of empyema. Of these, eleven were due to the pneumococcus, eight being due to the streptococcus, the empyema being an intercurrent affection in a general septic process. Of the other cases, one was tubercular, and in four various organisms were found, the empyema being secondary to perforation of the lung. I have not had the opportunity of seeing empyema follow an ordinary frank pneumonia of the whole lobe of the so-called sthenic type.

DR. H. F. VICKERY: It has been a trouble to me in treating cases where there is consolidation and also liquid outside of it to know when to endeavor to remove that liquid. It has seemed to me personally that a small amount did a good deal of harm by increasing the dyspnea, and yet my efforts to relieve the patient by removing the fluid have not been very reassuring. If you get it out early when it is still serum, it seems as if the raw pleura caused great pain. In the case of two patients I should like to be perfectly certain that it did not hurry their death. I think they would have died anyway. I got out a scanty pint of fluid in each case, and it did not afford the relief I expected. I do not know how Dr. Withington has made up his mind about that subject.

DR. WITHINGTON: In regard to Dr. Vickery's question, my feeling has been if the fluid were purulent and in any considerable amount it usually afforded some relief to the patient to aspirate it, and if it were serous fluid and large enough in amount to add very materially to the embarrassment of the respiration, then remove it. I think that a moderate amount of serous effusion in pneumonia is not of much consequence. It is not a complication, not a different thing engrafted upon the pneumonia, but simply a manifestation of the pneumonic bacterium in the pleura.

In regard to Dr. Mason's remark about the greater frequency of empyemata as a result of influenza, it ought to be said, on the other hand, that some of these cases which I have taken from the records of the hospital date back before this last epidemic visited us. Furthermore, the cases which Ewald speaks of in his compilation in the *Charité Annalen* of 1874 were in a time when epidemic influenza was not rife.

The question of nomenclature between parapneu-

monic and metapneumonic empyema is one which might be open to discussion, but the important fact in either case is the recognition of the relation of the empyema to the pneumonia. Whether it occurs along with it, as would be indicated by the term parapneumonic, or whether it occurs subsequently, as indicated by metapneumonic, might be perhaps open to some discussion. I have adopted the term metapneumonic, because it seemed to me that in most of these cases it was a matter of sequence rather than of simultaneous development. Many of these cases showed a typical resolution during the pneumonia, and after that a secondary rise and marked interruption of the progress of convalescence which was due to the development of the empyema after the crisis of the pneumonia itself had passed.

I believe Gerhard first used the term metapneumonic empyema, and it seemed to me a pretty fairly descriptive term.

I did not go into the question of treatment at all; but it seems to me the hint Dr. Mason gave is an important one as to the undesirability of removing a patient in the hospital down one or two flights of stairs and across to another wing of the hospital for operation when he is in a condition of exhaustion, as he is likely to be in with pneumonia and with the additional burden of a chest full of pus. Operation could be done in bed without the patient being transferred for that purpose. In other words, if you had such a patient in private practice, you would not subject him to such violent usage as would be involved in moving, and it is equally desirable in hospital practice that he be spared the same additional burden.

## THE NEW YORK NEUROLOGICAL SOCIETY.

STATED meeting, held at the New York Academy of Medicine, Tuesday evening, November 6, 1894, DR. EDWARD D. FISHER, President, in the chair.

DR. JAMES J. PUTNAM, of Boston, briefly reported the histories of

### FOUR CASES OF BRAIN SURGERY

recently coming under his observation. In all of these cases the chief symptoms were headache, nausea, vomiting and optic neuritis, and operation was advised for the purpose of relieving pressure. The first patient, a comparatively young man, did not recover from the effects of the ether, and died about five hours after the operation. No autopsy was permitted, but from an examination of the brain made through the opening in the skull evidences of a large hemorrhage underneath the cortex were found. The second case was that of a young girl who died during the etherization, before an incision had been made. At the autopsy three tumors were found in the situation where the skull had been about to be opened. In the third case the patient's symptoms were markedly relieved by the operation. In the fourth case a tumor of the cortex was found, and a large cyst underneath the cortex: the latter was emptied, but it rapidly refilled, and during the past few days there has been some oozing of brain substance from the wound, and the patient is likely to do badly. These cases, the speaker said, go to show the dangers that attend opening the skull, which is usually regarded as a comparatively simple operation.

DR. M. ALLEN STARR gave an

### EXHIBITION OF MICRO-PHOTOGRAPHS OF NERVE CELLS (GOLGI'S STAINS).

These photographs were made by Dr. Edward Leaming, Instructor of Micro-photography at the College of Physicians and Surgeons, from specimens prepared by Mr. Strong, in the laboratory of the Biological Department at Columbia College. They showed various portions of nerve tissue, some stained by Golgi's method and others by a modification of that method employed by Mr. Strong. These micro-photographs, Dr. Starr said, were exhibited this year at the British Association at Oxford, and received a good deal of favorable comment. One of them, showing the Purkinje ganglion-cell, took the prize in London for the best exhibit of micro-photography.

DR. C. L. DANA read a note on

### A CASE OF ACUTE POLIOMYELITIS IN A HEN.

The speaker stated that during the past summer, in the months of July and August, there occurred in the neighborhood of Rutland, Vt., an epidemic of anterior poliomyelitis. Dr. Caverly, the health officer of the State, said that during this epidemic horses and fowls became affected, and on September 18th he sent to Dr. Dana a large Plymouth Rock hen for bacteriological purposes. This fowl, on its arrival here, was paralyzed; and the owner of the flock, a physician, reported that several had died, the symptoms being similar to those noted in this one. The hen was taken to the Carnegie Laboratory, and a careful clinical examination made, which revealed a paraplegia (not quite complete) and some paralysis of the wings; the head and neck muscles were not affected; there was no anesthesia. Dr. Dunham, who conducted the bacteriological examination, inoculated several culture tubes from the spinal cord and meninges, and also took several sections from the cord and made smear stains, all with a negative result. The spinal canal of the animal was opened, and no evidence of meningitis was found, nor were there any signs of hemorrhagic extravasation. On being placed in Müller's fluid and stained, a distinct area of softened tissue was seen in the central part of what might be termed the lumbar region of the cord. The destructive process was quite extensive; the congestion was intense, and there were several hemorrhages. From the appearance of the cord it appeared that there had been an acute exudative inflammation, and that the process was so severe that necrosis came on before the inflammatory reaction; hence it is practically a case of acute infectious softening rather than myelitis. In conclusion, Dr. Dana said that while this case might not have any actual value, yet to a certain extent it corroborated the infectious theory of anterior poliomyelitis, and, so far as it went, it supported the view that in this disease the changes were primarily vascular and not parenchymatous.

DR. PUTNAM stated that at an autopsy made in a case of anterior poliomyelitis of two months' standing in an adult, he found that the necrotic process was distinctly confined to the area immediately surrounding the vessels.

DR. STARR stated that while on a visit to Vermont last summer, he saw a number of the cases of anterior poliomyelitis referred to by Dr. Dana. Within a radius of perhaps twenty-five miles, about 160 cases of

the disease occurred between the 25th of July and the 1st of September. Dr. Starr said he saw about a dozen of these cases. The epidemic was first regarded as one of cerebro-spinal meningitis; but from the lack of sensory symptoms and the peculiar distribution of the motor symptoms, the speaker said he regarded them as true cases of anterior poliomyelitis. Sensory symptoms were present in some of the cases; but he has often found an anterior poliomyelitis in children over the age of twelve years and that hyperesthesia and stiffness of the muscles are among the first symptoms complained of.

Dr. B. Sachs said that in France the tendency has been to regard anterior poliomyelitis as epidemic. Epidemics of the disease have been observed in Stockholm. In his own practice he has noticed that by far the larger number occur during the warm weather. It is probable that we must include this affection among the acute infectious diseases which are epidemic, or rather endemic. He has observed cases where it was difficult at first to say whether the disease was cerebro-spinal meningitis or anterior poliomyelitis. In several cases of the latter disease in the very early stage, pain along definite nerve tracts was a very characteristic symptom.

Dr. A. Jacobi stated that last August he received a letter from Dr. Caverly regarding this epidemic in Vermont, in which he described a number of the cases, particularly emphasizing the fact that there was a good deal of hyperesthesia. Basing his conclusion on these data, Dr. Jacobi said, he expressed the opinion that the epidemic was one of cerebro-spinal meningitis, as the manifestations of that disease differ widely at times. Since then, however, he had received more detailed information regarding the cases from Dr. Starr, who examined a number of the patients, and he now had no doubt that the epidemic was one of anterior poliomyelitis.

Dr. A. D. Rockwell stated that two of these cases were examined by him. In one the hyperesthesia was very distinct, and he was inclined to regard them as cases of cerebro-spinal meningitis.

Dr. Starr called attention to the fact that in the classical descriptions of anterior poliomyelitis, so little mention is made of the pain and stiffness and hyperesthesia. The reason for this probably is that so few cases of the disease are diagnosticated as such until they have gone on for a week or two, and by that time the sensory symptoms have practically disappeared. If this newer pathology of the disease is correct, and it is due to a congestion of the cord, sensory symptoms are undoubtedly present.

Dr. Putnam said that in the case already referred to by him, the hyperesthesia was excessive; so much so, that he could hardly doubt that peripheral neuritis was also present. In all other respects the symptoms were typical of anterior poliomyelitis.

Dr. A. Jacobi said there are two distinct classes of cases in this disease. In one class, that referred to by Dr. Starr, there is fever and hyperesthesia at the beginning, but these symptoms are readily obscured in cases where the myelitis comes on during the course of another disease, such as scarlet fever, pneumonia, etc. The acute symptoms are ascribed to the latter disease, upon recovery from which it is found that the child is paralyzed. In the other class of cases, and probably the large majority are of this character, the child is put to bed quite well, and when it is taken up in the morning it is found to be paralyzed; there is no fever and no hyperesthesia; there is not even an outcry in the night.

Dr. Landon Carter Gray said he agreed with Dr. Jacobi that cases of anterior poliomyelitis like those last described were very commonly met with; yet there were a certain number where the patients had unquestionable sensory symptoms, which we were often apt to attribute to a neuritis. It was a fact that this disease usually occurred during the hotter months. This subject was carefully studied some years ago by Drs. Weir Mitchell and Sinkler; they also showed that chorea was not dependent on temperature, but rather on barometric fluctuations.

Dr. G. M. Hammond inquired whether the diagnosis in the hen was based on the clinical symptoms or the pathological condition of the cord. In anterior poliomyelitis we were apt to associate a certain group of symptoms with certain pathological changes in the cord. In the microscopical sections exhibited by Dr. Dana the anterior horns appeared to be symmetrical, and the changes did not exactly resemble those we found in the true disease.

Dr. Dana replied that in some of the sections, which he had been unable to bring with him, the lesion in the cord was very marked. In some there was a distinct loss of substance, with softening and hemorrhage.

The President said that in the differential diagnosis between anterior poliomyelitis and cerebro-spinal meningitis, the extreme muscular atrophy which we find in the former would not be so apt to be present in the latter. The electrical reactions, too, might aid us. Sensory symptoms, he thought, were often present in anterior poliomyelitis, and were apt to be overlooked.

### SOME OF THE IMPORTANT ASPECTS OF THE THERAPEUTICS OF DISEASES OF THE NERVOUS SYSTEM.

Dr. James J. Putnam, of Boston, read an interesting paper on this subject. The main portion of his paper was devoted to a critical study of psychical therapeutics, or mental influence in certain forms of nervous disease with special reference to neurasthenia. This method of treatment, systematically carried out, often produces excellent results, not alone in functional, but even in organic nervous disease. Among the methods of psychical influence employed by him, the author mentioned static electricity as one of special value. As regards electro-therapeutics in general, he is not prepared to accept the dictum of certain French writers, and assert that its benefit is wholly due to its influence on the mind. Among other forms of mental influence, Dr. Putnam mentioned waking and hypnotic suggestion: as regards hypnotism, he stated that while he is not particularly in favor of it, the time has come when we ought to recognize what there is of value in it. This agent should never be employed excepting by one who is skilled in its use, or, if the patient's own physician undertakes it, he should be content to induce a moderate degree of hypnotism. In one case coming under his observation, a young woman with spastic paraplegia of several years' standing, numerous attempts made to hypnotize her never succeeded beyond the production of the first stage; through suggestions made to her while in this condition she partially regained the use of her legs, and the improvement has been permanent.

Among other therapeutic measures referred to by

the author, which he has found valuable, especially among dispensary patients, where the need of better methods for the treatment of nervous diseases has long been felt, were gymnastics, including the formation of classes for calisthenics, massage and hydro-therapeutics. During the past year he has treated fifteen cases of chronic spinal sclerosis by suspension, a method of treatment which he regards as wholly empirical. In almost every instance these patients declared themselves improved, both as regards eyesight and general condition.

In concluding his paper, Dr. Putnam stated that during the past few months he had tested the Flechsig treatment of epilepsy by means of large doses of opium; and he referred to a paper on this subject by Dr. Joseph Collins (*New York Medical Record*, September 22, 1894). The treatment was employed in ten cases; in none of them were the attacks wholly checked, but in all of them an improvement was noted. The opium was never pushed beyond ten grains daily.

DR. GRAY said that in some patients there is such an admixture of the symptoms of neurasthenia, hypochondriasis and hysteria that it is difficult to distinguish one condition from the other. There are, on the other hand, cases which we may term pure neurasthenia; and it is in these cases, as he understood the paper, that the author would employ hypnotism under the broad term of suggestion. Hypnotism, in the way that it is generally used, is an agent that we can seldom employ in neurasthenia, not only because there is a prejudice against it, but also because it is difficult to impress such patients favorably by means of it. The same thing may be said about it in hypochondriasis, while on the other hand, in hysteria its results are peculiarly favorable. As regards the value of electro-therapeutics, Dr. Gray said he was firmly convinced that the benefit following its employment in certain conditions was by no means confined to its influence on the mind of the patient. He had over and over again seen cases of neuritis in an advanced stage improve under the galvanic and faradic currents. He had seen marked benefit follow the use of this agent in many cases of anterior poliomyelitis and muscular atrophy.

DR. WILLIAM H. THOMSON referred to the value of newness or change as a psychical therapeutic measure in nervous diseases, and narrated the histories of a number of cases in which remarkable improvement followed the change of scene and surroundings.

DR. SACHS said it was claimed by some that hypnotism had not met with the reception in America which it deserved, and that one reason for this was that we were still subject to the old idea that the physician must prescribe; that we were altogether too fond of drugs. Personally, he regarded it as a therapeutic measure which was of value in comparatively few cases. After a thorough and impartial trial, his own experience with it had been anything but satisfactory.

DR. MARY PUTNAM JACOBI stated that she had found static electricity almost a specific for the purpose of dissipating muscular pains, whether rheumatic, hysterical or otherwise, even if such pain had entirely resisted the galvanic or faradic currents.

DR. ROCKWELL said he had employed statical electricity for many years, and expressed the opinion that its value had been very much over-estimated; its slight quantity gave it little value as compared with other forms of electricity.

DR. STARR said it seemed to him that the reason why Dr. Weir Mitchell's rest treatment was so successful was that it combined most of the different elements which had been mentioned by the various speakers. There was first the expectation of taking a cure which had been of benefit to others; this was combined with a trip to Philadelphia, a change of scene, and an entire change in the daily routine of life. The speaker also referred to the value of hydro-therapeutics, which made an intense mental impression on the patient.

DR. MARY PUTNAM JACOBI said that one writer, probably humorously inclined, had made the assertion that the beneficial effects of hydro-therapeutics were more pronounced in France than in England, because no French person ever takes a bath.

DR. JOSEPH COLLINS said he recently had the opportunity of discussing the Flechsig treatment of epilepsy with its originator, who, although not so enthusiastic regarding it as he was at first, still considered it of great value.

DR. PUTNAM then closed the discussion.

At the close of the discussion, a vote of thanks was given to Dr. Putnam by the Society for his interesting and able paper.

## Recent Literature.

*The Medical News Visiting List for* 1895. Weekly (dated, for 30 patients); Monthly (undated, for 120 patients per month); Perpetual (undated, for 30 patients weekly per year; and Perpetual (undated, for 60 patients weekly per year). The first three styles contain 32 pages of data and 160 pages of blanks. The 60-Patient Perpetual consists of 256 pages of blanks. Each style in one wallet-shaped book, with pocket, pencil and rubber. Philadelphia: Lea Brothers & Co. 1894.

The Medical News Visiting List for 1895 has been thoroughly revised and brought up to date. The text contains useful data for the physician and surgeon, including an alphabetical Table of Diseases, with the most approved remedies and a table of doses; sections on examination of urine, artificial respiration, incompatibles, poisons and antidotes, diagnostic table of eruptive fevers, and the ligation of arteries. The classified blanks hold records of all kinds of professional work, with memoranda and accounts. It is one of the most convenient of the visiting lists published.

*Dissections Illustrated.* A Graphic Handbook for Students of Human Anatomy. By C. GORDON BRODIE, F.R.C.S., etc. With plates drawn and lithographed by PERCY HIGHLEY. In four parts. Part III, The Head, Neck and Thorax. London & New York: Whittaker & Co. Macmillan & Co., Publishers.

We have already spoken of the first two parts of this work. The dissections are beautiful and they receive full justice in the colored illustrations. The worst that is to be said in criticism is that the style of anatomy is that of the older English school.

NEW EDITOR OF THE ARCHIVS FÜR KLINISCHE CHIRURGIE. — Professor Gussenbauer, of Vienna, has been chosen to take the place of the late Professor Billroth on the editorial staff of this journal.

## REPORT OF THE SURGEON-GENERAL OF THE UNITED STATES NAVY.

THE report of the Surgeon-General of the United States Navy embraces a "statement of the condition of the naval hospital fund, the naval medical establishment and other matters of interest pertaining to the duties of the Bureau of Medicine and Surgery." Certain of the *other* matters cannot fail to interest every one who is interested in the welfare of the new navy of which we have heard so much during the last few years.

One reads and hears so much concerning the *personnel* of the navy that the little the surgeon-general has to say on the subject of recruiting naturally attracts attention; and under that head one reads as follows: "Enlistments on sea-going ships should be prohibited by regulation, from the fact that many of our new ships are unprovided with suitable accommodations for such examination, some of them having no examining-rooms or sick-bays, and even in those having sick-quarters they are entirely inadequate for the proper performance of this work."

There is something quite startling about this lack of accommodation for the sick and wounded. It is entirely at variance with the forethought to be expected; and one looks with interest through the rest of the report to see what further can be found regarding sick-quarters in our new vessels which have been held up as a source of national pride.

The next information on the subject is given under the heading of sick-quarters on board vessels of war, where it is stated that "on board of ten vessels no quarters are designated for the treatment of the sick and wounded; in the case of the *Minneapolis* the omission was probably due to an oversight, as this vessel was designed on similar lines to her sistership, the *Columbia*." Some of the reports from the different vessels give more particulars. The medical inspector's report on the U. S. S. *New York*, contains the following: "The sick-bay is in the same part of the ship that it has been for ages past, in the bow, on the berth-deck, having only a torpedo operating-room forward of it. . . . The forward torpedo is operated through the sick-bay while the blacksmith's forge is overhead. The noise of the huge cables running through the steel pipes that pass through the sick-bay is deafening, causing the patients to hold their heads in agony. . . . The operating-room, so called, is the bath-room and water-closet." The surgeon of the *Detroit* reports as follows: "The ship has no sick-bay. This is a most deplorable fact to contemplate on board of any sea-going ship; bad enough where the berthing spaces are sufficiently large and well ventilated to give fair comfort to men in good health, and where the sick may be isolated by temporarily depriving others of their regular berths, but in a ship of this class where every dry, ventilated and not overheated space is crowded beyond its healthful capacity, the absence of a proper place for the treatment and care of the sick is not only a source of annoyance and discomfort to others, but is fraught with no little danger to the unfortunate sailor."

These startling statements are given in the very words of their writers, and represent a strange state of things — which evidently does not exist without a protest on the part of the surgeon-general. "A special report relating to the importance of providing suitable accommodations on board of our ships for the care and treatment of the sick and wounded of the navy has already been submitted to the Department. The plans of all vessels in commission, undergoing construction and nearing completion, have been carefully examined with a view of selecting suitable location for sick-quarters, and recommendations made when required."

The medical inspector on the *San Francisco* speaks pleasantly of the naval militia, as follows: "They came on board full of enthusiasm and good-will, and while here devoted themselves to their duties and embraced every opportunity for the acquirement of a knowledge of the exercises of a vessel of war. The surgeon of the Massachusetts battalion came with them. He held a regular sick-call, and used his own medicines and instruments."

The "Department of Instruction" in connection with the U. S. Naval Laboratory at New York, is spoken of in the most routine manner. A system of instruction for assistant-surgeons immediately after passing a successful examination for admission into the medical corps of the navy, was created by a regulation issued by the Department over a year ago. Following the nomenclature elsewhere adopted, it might be called the Naval Medical School. It would be of general interest to know a little more about the work expected of the young assistant-surgeons and the advantages for post-graduate study given them. At the last meeting of the Association of Military Surgeons of the United States it was stated that the medical officers of the navy would gladly see the privileges of this school extended to the officers of the naval militia.

## THE CITY INSANE ASYLUMS ON WARD'S ISLAND, NEW YORK.

ON December 26th, the State Commission in Lunacy, of which Dr. Carlos F. MacDonald is chairman, made public the report of the investigation into the condition of the city asylums for the insane on Ward's Island, which it commenced last summer. In May, last, charges were formulated against the administration of these institutions, and, in consequence, the Mayor addressed a letter to the Commission, asking an immediate investigation. Regarding the charge that the Commissioners of Charities and Correction were negligent of their duties and had diverted moneys intended for the erection and repair of asylum buildings to other purposes, the report finds that the Commissioners failed of effective supervision by joint visitation and inspection, but, in view of the large number of institutions under their charge, that they did the best they could under the circumstances. As to the incompetency, neglect and inefficiency of the General Superintendent and other medical officers, the report finds the charges not sustained and commends all these officials. The report also considers inadequate and biased the testimony in relation to the character and conduct of the nurses and attendants. It maintains that, despite the safeguards of the probationary term and the civil-service examination, an unsuitable person will occasionally gain admittance to the service, and that while in certain occasional instances cases of neglect and ill-treatment of patients were brought to light, the offender was always promptly discharged when the facts became known to the Superintendent. As a rule, the attendants were found faithful to their trust and deserving of the confidence of their superior officers.

The report goes on to state that the attendants were justified in certain complaints they had made and condemns the proportion of attendants (one to sixteen patients) as entirely inadequate and in marked contrast to the proportion in the State hospitals for the insane. It sustains the charges made as to the insufficiency and poor quality of the food furnished, and finds fault with the character and amount of the furniture, clothing and bedding provided. The charge regarding a scarcity of alcoholic stimulants is not sustained, but the supply of medical and surgical appliances is found to be not as complete as it should be. Regarding the existence of scurvy and the overdosing of patients, the Commission does not think the evidence produced sustains either charge, but it does condemn the use of dangerous medicines in such large doses as in certain instances were indicated in the testimony. The charges that the female patients were overworked and that infectious cases were not properly isolated are not sustained. It is admitted, however, that patients suffering from pulmonary tuberculosis were not isolated, but this is regarded as impossible on account of the overcrowded condition of the wards.

The charges of overcrowding, dilapidation, defective plumbing, ventilation, etc., are fully sustained, and the asylums are found to be overcrowded to the extent of 2,500 patients. The various charges having been disposed of, the report proceeds to discuss the causes of the existing abuses, and the conclusion is arrived at that they are due to the system under which these institutions are organized and administered, rather than to any particular individual officials or set of officials. In conclusion, the report presents a strong argument in favor of the transfer of the city's asylums to the care of the State.

## THE BERLIN MEDICAL SOCIETY ON DIPHTHERIA ANTITOXIN.

THE Berlin Medical Society has been engaged in a discussion of the method of action and of the merits of the serum treatment of diphtheria. Dr. Hansemann, of Professor Virchow's pathological laboratory, led in an attack upon the diagnostic, etiological value of the Klebs-Löffler bacillus, and the value of the serum as a specific remedy.

Virchow pronounced the theory forming the basis of Behring's entire antitoxic theory to be a fallacy, but at the same time acknowledged that "all theoretical considerations must give way to the *brute force* of figures." There is certainly much "brute force" in the figures adduced by Professor Virchow as taken from the records of the Kaiser and Kaiserin Friedrich Hospitals. In June and July nearly all diphtheria cases were treated with the serum, and results were remarkably good, there being only eight deaths in 63 cases; the supply of serum then gave out, and in 109 cases treated without serum during the next seven weeks there were 55 deaths; a new supply of serum was then obtained and in 81 cases treated with it during the next six weeks there were only 12 deaths. In the whole period, 533 cases were treated — 303 with serum, 230 without. Among the former there were 13.2 per cent. of deaths; among the latter, 47.8 per cent. of deaths.

In view of such results, Professor Virchow naturally holds, notwithstanding his opinion as to the fallacy of the theoretical basis of the antitoxin treatment, that it is the duty of every practitioner to use the serum in diphtheria.

## THE POSITION OF THE PHILADELPHIA HOSPITAL TRUSTEES.

WE commented briefly last week upon the extraordinary action of the trustees of the Philadelphia Hospital in summarily dropping from the hospital staff Dr. Judson Daland, for apparently no other reason than that he postponed active therapeutic measures in the case of a malarial patient in order to study the case and verify the diagnosis by the aid of modern scientific methods.

The question thus presented is a much broader one than its mere effect upon an individual. It concerns the proper relation of hospitals to the public, and the

duties of their medical and lay officers to both hospitals and the public. We are glad, though not surprised to learn that it is thus regarded by Dr. H. A. Hare, whom the trustees of the Philadelphia Hospital appointed to the vacancy so summarily made, and who has declined an appointment given under such circumstances. Any physician holding his profession in honor, must perforce do the same. We hope a further study by the trustees of this hasty and ill-considered action, in all its bearings, will lead them to its revision in a liberal, comprehensive, intelligent spirit, and to the reinstatement of Dr. Daland.

## MEDICAL NOTES.

CHOLERA IN ARGENTINA. — An epidemic of cholera is reported to have broken out at Rosario and Colastine in Argentina. Although there have been but few deaths the disease has been determined to be true cholera, and the ports have been closed against traffic.

AFTER-EFFECTS OF ANTITOXIN. — Rembold reports in the *Deutsche Med. Wochenschrift*, for December 20th, two cases out of six treated with antitoxin which showed the urticarial eruption, with constitutional symptoms, following the antitoxin treatment. These cases were in every respect similar to those reported by Cuyrim and Zublinski, and noticed in the JOURNAL for December 20th. In one of these cases though the effect of the antitoxin in the acute stage of the diphtheria was markedly beneficial, post-diphtheritic paralysis of accommodation ensued.

COMMERCIALIZATION OF SERUM THERAPY. — It is reported that the shares in the Höchst establishment for the production of antitoxin rose several points recently on the Frankfort Stock Exchange, on the strength of a report that the works were about to put on the market a typhoid antitoxin discovered by Behring! The results of such commercialization of the name of Koch are too recent to be forgotten.

A NATIONAL DIPHTHERIA COMMISSION. — According to the *Journal of the American Medical Association*, Representative Goldzier, of Illinois, has prepared and will endeavor to secure the prompt adoption of a joint resolution for the creation of a National Commission for the investigation of the antitoxin treatment of diphtheria.

A SNAKE STORY VERIFIED. — A surgeon who doubted the story of the male python in the London Zoölogical Garden having swallowed his mate, and claimed that the reptile might have in some way crawled out of the cage, is reported by the *Medical Press* to have had his doubts set at rest by the discovery of several vertebræ of the defunct reptile among the feces of the survivor. The surgeon now has the vertebræ in his possession.

A PUGILIST'S VIEWS ON FOOTBALL. — Mr. Robert Fitzsimmons, a pugilist, who in a recent exhibition dealt his sparring partner a fatal blow, has been looking up the records, and informs the public that during the last ten years only twenty-three men have died of injuries received in the prize-ring, and that during the months of November and December there were twelve fatal football accidents. He therefore concludes that football is fifty times as dangerous as sparring. In his calculations he evidently forgets that inasmuch as November and December are the only two months in which football contests take place, during those two months there are probably more men engaged in playing football during one season, than there have been engaged in professional pugilistic contests for the last ten years.

A FATAL CASE OF CHICKEN-POX. — Nisbet reports, in the *Australasian Medical Gazette*, for November 15, 1894, a case of uncomplicated chicken-pox in a child eight and a half months old, which proved fatal, owing, in his opinion, to the fact that the eruption covered every part of the body, even the palms of the hands and soles of the feet, and produced practically the same effect as an extensive burn. On the seventh day of the disease spots appeared in the mouth, which changed to irritable ulcers, causing great distress. Death occurred on the tenth day. Dr. Nisbet thinks that there was no question as to diagnosis, as four older children in the same house were ill with the disease, and there was an epidemic in the town at the time. Collie, in "Quain's Dictionary of Medicine," states that "no physician has recorded a fatal case of chicken-pox."

### BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, December 26, 1894, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 86, scarlet fever 62, measles 50, typhoid fever 12. During the week ending at noon, January 2, 1895, the following cases were reported: diphtheria 64, scarlet fever 54, measles 51, typhoid fever 4.

A DANGEROUS COSMETIC. — A four-ounce bottle of a certain face bleach examined by the State Board of Health during November was found to contain twenty-seven grains of corrosive sublimate.

DEATH OF A CENTENARIAN. — Mrs. Alma Ida Reynolds died at East Dedham, December 22d, aged one hundred years and eleven months. She was born in Eastford, Conn., in 1794, and was in good health until the last year of her life.

SEMI-CENTENNIAL OF THE DISCOVERY OF ANESTHESIA. — The Harvard Odontological Society, in conjunction with the Harvard Dental Alumni Association, held a meeting on December 26th, for the purpose of celebrating the discovery of anesthesia by Horace Wells, fifty years ago.

THE NINETEENTH REPORT OF THE SALEM HOSPITAL. — This report, that for the year 1893, shows that during that year 318 patients were treated, 178 medical and 140 surgical. Dr. Hardy Phippen was

appointed a member of the surgical out-patient staff. Five pupils were graduated from the training-school for nurses, and 531 cases were treated at the out-patient department during the year.

THE AMERICAN CHEMICAL SOCIETY. — This society held a general meeting in Boston on December 28th and 29th. It was reassuring to learn from the speech of the retiring president that chemistry had not yet reached the stage at which synthetic food products could be produced, and that the "beefsteak of the future," at least the immediate future, would not take the form of a compressed tablet, manufactured by some well-known and reliable firm, and "containing all the nutritive properties of a pound of beef." As an advantage of these tablets it would undoubtedly be claimed, that "inasmuch as our tablets are purely synthetic in composition, by their substitution for beef all danger from bovine tuberculosis is eliminated." With this prospect in view the work of the Cattle Commission would be viewed as an entirely unnecessary expense.

A LABORATORY FOR THE MASSACHUSETTS CATTLE COMMISSION. — The great increase in laboratory work necessitated by the attack on bovine tuberculosis, has made it necessary for the Cattle Commission to establish a laboratory to be devoted exclusively to its own use. The work has heretofore been done chiefly at the pathological laboratory of the Harvard Medical School, and at the Massachusetts Agricultural College at Amherst. The new laboratory is being fitted up at 50 Village Street, the present headquarters of the board, and the work is to be under the direction of Dr. W. F. Whitney.

THE ATTITUDE OF THE FARMERS TOWARD THE CATTLE COMMISSION. — Reports from various parts of Massachusetts indicate that in proportion as the farmers have the opportunity to see the work of the cattle commissioners, and become acquainted with the certainty of the tuberculin test, they realize the importance of having their herds purified. The protests about the unreliability of the test, and its alleged danger to healthy cattle are becoming fewer, and the owners of herds are apparently realizing that unless they show a willingness to have tuberculosis stamped out they will stand in a very bad light before public opinion in comparison with the more intelligent cattle owners, some of whom at their own expense had their herds examined before they were obliged to do so by law. On the question of compensation, however, most of the farmers still insist that they ought to receive for the loss of a diseased animal the full value of a healthy one.

## NEW YORK.

THE ASSOCIATION OF AMERICAN ANATOMISTS. — The seventh annual meeting of the Association of American Anatomists was held at the College of Physicians and Surgeons on December 28th and 29th. Among those who were present and read papers were Drs. Thomas Dwight, of Boston, Burt G. Wilder, of Cornell University, Harrison Allen, of Philadelphia, D. S. Lamb, of Washington, and E. C. Spitzka, of New York.

DEATH OF DR. DETMOLD. — The venerable Dr. William Detmold, the distinguished surgeon, died December 26th. Dr. Detmold was born December 27, 1808, in Hanover, where his father was physician to the king. He was graduated at Göttingen in 1830, and came to New York in 1837. He was one of the first to practice orthopedic surgery in this country and established an orthopedic clinic at the College of Physicians and Surgeons. At the time of his death he was emeritus professor of clinical and military surgery at that institution. When the New York County Medical Association was organized in 1884, Dr. Detmold was selected as its first president, and he was also one of the founders of the New York State Medical Association.

DIPHTHERIA AT THE MOUNT VERNON BRANCH OF THE NEW YORK INFANT ASYLUM. — Since the end of September diphtheria has prevailed to a considerable extent at the Mount Vernon Branch of the New York Infant Asylum, and it was found necessary to set apart three of the cottages at the institution for those suffering from the disease. Up to the present time there have been over eighty cases and about sixteen deaths. Recently antitoxin has been used in the treatment (a portion of the supply having been obtained from Berlin and a portion from the New York Pasteur Institute), and, while the number of cases thus treated is not large, no death is said to have occurred among them. Dr. Peck, one of the resident physicians, who was attacked by the disease a short time since, was among those treated with antitoxin.

AN EXPENSIVE ATTACK OF RABIES. — On December 21st a rabid dog bit no less than sixteen persons in the town of Salem, N. J., and of these seven are now under treatment at the New York Pasteur Institute. Others of those bitten will also be sent on for treatment, and it is stated that the total expense, amounting to over one thousand dollars, will be borne by the Salem Glass Works Company.

EXAMINATION OF CATTLE FOR TUBERCULOSIS. — The State Board of Health has made a report of the work accomplished during the first year under the law relating to examination of cattle for tuberculosis. "There can no longer be a reasonable doubt," the report says, "that cattle suffering from tuberculosis are extensively distributed through the dairies of the State, forming centres of infection in their respective herds; that the milk from such cattle is bad, and in many cases, though not acting perniciously upon all who partake of it, is still sufficiently dangerous to warrant as earnest precautions and as effective prophylactic measures as in the cases of small-pox, typhoid and cholera. The appropriations made, though incommensurate with the magnitude of the undertaking, have been sufficient to show to some extent the vast proportions of this menace to life and health and the need of adequate resources to intelligently meet and overcome it."

## Miscellany.

### THE ANTITOXIN TREATMENT IN LONDON.

Washburn, Goodall, and Card, in the *Lancet* for December 22d, report the results of 72 cases of diphtheria treated with antitoxin in London between October 23d and November 27th. In 61 of the cases the Klebs-Löffler bacillus was found in the fauces. In 45 cases streptococci were associated in large numbers. There were 14 deaths, or 19.4 per cent. The average mortality in the same hospital during 1893, and up to October 22, 1894, was 38.8 per cent. The mortality of the 72 cases immediately preceding the beginning of the antitoxin treatment was 38.8 per cent. In the opinion of the writers the cases treated with antitoxin were of more than average severity. From October 23d to November 27th, the mortality from diphtheria at three other London hospitals where antitoxin was not employed was 33.3, 32.2, and 23.3 per cent. Tracheotomy was performed in nine of the cases treated with antitoxin, three of which died and six recovered. In 13 previous series of nine tracheotomies, the recoveries had varied from zero to four, the average of the recoveries per series being 1.75. According to the observations of the writers, and contrary to most previous statements, the association of the streptococcus did not appear to affect unfavorably the course of the disease, or the results of the antitoxin treatment.

### A FUND FOR A BRONZE STATUE TO CHARCOT.

The pupils and former associates of Charcot in Paris and throughout France are engaged in raising a fund for the erection of a bronze statue of him in the Sàlpêtrière. This movement is receiving cordial and material support in Germany, England and Italy.

It has therefore seemed desirable to the Neurological Societies of New York and Philadelphia that the profession in America join in this testimonial, as an evidence of the eminent services of Charcot in neurology and medicine. The undersigned have been appointed a committee to bring the matter to the attention of the profession and to receive contributions, which will be duly acknowledged and forwarded to the central committee in Paris.

It is requested that all who desire to contribute to the success of this undertaking send their subscriptions to the members of the committee nearest to them or direct to the treasurer, Dr. C. A. Herter, 819 Madison Avenue, New York, before the first day of February, 1895.

E. D. Fischer, M.D., E. C. Seguin, M.D., M. A. Starr, M.D., C. L. Dana, M.D., C. A. Herter, M.D., *for New York.*
S. Weir Mitchell, M.D., Wharton Sinkler, M.D., Chas. K. Mills, M.D., *for Philadelphia.*
J. J. Putnam, M.D., P. C. Knapp, M.D., *for Boston.*
William Osler, M.D., *for Baltimore.*
Archibald Church, M.D., *for Chicago.*
C. H. Hughes, M.D., F. R. Fry, M.D., L. Bremer, M.D., *for St. Louis.*
James Stewart, M.D., *for Montreal, Canada.*
E. B. Angell, M.D., *for Rochester.*
J. W. Putnam, M.D., *for Buffalo.*
Theodore Diller, M.D., *for Pittsburgh.*
Howell T. Pershing, M.D., *for Denver.*
J. D. Hirschfelder, M.D., *for San Francisco.*

December 22, 1894.

### TREPHINING IN MENINGITIS.

Nearly coincident with the editorial in the Journal for December 20th on "Trephining for Tuberculous Meningitis," comes the account in the December number of the *International Medical Magazine* of a case of trephining for the removal of fluid in a case of acute cerebral meningitis, by B. Merrill Ricketts, M.D.

The operation, done, of course, for the relief of intra-cranial pressure, was performed on the tenth or eleventh day of the disease, in a case of meningitis following an attack of whooping-cough. The child was in very poor condition, with a high temperature, rapid pulse, pupils non-reacting, coma, complete motor paralysis, and retention of urine. No nourishment had been taken for twenty-four hours; there was paresis of the left facial nerve, and of the muscles of deglutition. Emaciation was excessive.

Two openings were made with the chisel, over the right and left parietal bones respectively. On opening the arachnoid cavity large quantities of serous fluid escaped and continued to flow. Immediately after the operation the child cried, and was able to move its limbs. The respirations fell from fifty to thirty, urine was passed freely, and sufficient nourishment was taken. The improvement continued for a few hours only, when the child began to fail, and died twenty-eight hours after the operation. The flow of fluid continued till death.

While the relief of cerebral pressure can be said to give these cases their only chance, death has so far only been postponed. Effective drainage will be found to be even more difficult in the case of the cranial cavity than in the abdominal. The impossibility of disinfecting these cavities, on account of their many ramifications and the delicate structure of their walls, in addition to their liability to rapid absorption of septic material, renders the successful surgical treatment of acute inflammation extremely difficult. Successful operations upon acute peritonitis are among the greatest rarities; and none upon acute meningitis has so far been recorded. It is a matter of extreme interest that the operative cure of chronic tuberculous inflammation, which has been accomplished in so many cases of abdominal tuberculosis, has been extended in one case to meningeal tuberculosis.

With regard to meningeal sepsis, Ricketts says: "As it is, nearly all these cases die without operation. The question now is, Will any of them be benefited or cured if operated upon during any particular time in the course of the disease?"

Although the clinical history of Dr. Rickett's case points rather to an acute tubercular than to a septic process, his remarks will apply to acute cases. It is unfortunate that cultures were not taken in either of the cases alluded to.

### A CASE OF TUBERCULAR MENINGITIS; DIAGNOSIS BY LUMBAR PUNCTURE; RECOVERY.

The cases reported in medical literature of apparent recovery from tubercular meningitis naturally admit of doubt, for it is well known that errors of diagnosis are very common. Fürbringer, in the *Deutsche Med. Wochenschrift*, 1894, No. 36, reports a case in which the diagnosis was established beyond a doubt. The case was that of a laborer, twenty years of age, who while in the best of health was taken with severe

headache and fever. Various symptoms pointing to the central nervous system led to a diagnosis of meningitis. In order to establish the diagnosis, Fürbringer performed paracentesis of the spinal canal at the level of the second lumbar vertebra; 60 c. c. of a slightly cloudy serous fluid escaped, in the sediment of which were found a few pus corpuscles and numerous tubercle bacilli. Contrary to all expectation the fever subsided after the puncture, the sensorium became clear, the headaches gradually disappeared, as well as the rigidity of the extremities and of the spinal column. Convalescence was uninterrupted and the patient was discharged cured.

Although, as is acknowledged by the *St. Petersburger Med. Wochenschrift*, November 19, 1894, the therapeutic value of the lumbar puncture introduced by Quincke, after numerous trials, still admits of doubt, the method certainly is applicable, as claimed by that journal, for diagnostic purposes, and the more so that tubercular meningitis often takes the cerebro-spinal form.

## A MINDLESS FROG.

AT the meeting of the Association of American Anatomists in New York on Saturday, December 29th, Prof. B. G. Wilder showed a frog from which, under ether, the entire cerebrum was removed on the 7th, three weeks before. It looked natural. The scar on the head was hardly visible. It can swim and jump and even balance on a cylinder while it is slowly turned, and swallow food that is placed far back in the throat. But when undisturbed it sits without motion, and presumably has no consciousness. That such a frog, while in possession of all his senses (excepting smell, the olfactory lobes being removed with the cerebrum) has no real "sense" may be seen from the behavior of a similar specimen shown the American Neurological Association in 1886. A minnow was put into the mouth. The head reached the throat and aroused the swallowing reflex; but the tail protruded from the lips and caused the frog to put up his hands to push it out. The normal frog would have decided whether the fish should go up or down. The decerebrized animal was a mere reflex machine and could make no choice between incompatible operations.

# Correspondence.

## NOTES ON ANTITOXIN.

NEWTON, MASS., December 29, 1894.

MR. EDITOR: — Within the past few weeks I have used in three cases the diphtheria antitoxin, made by Dr. Paul Gibier in the Pasteur Institute of New York, as a prophylactic agent in doses of five cubic centimetres. A dermatitis has occurred about the site of injection in each case.

In the first patient, a baby of eighteen months, an erythematous eruption occurred on the day following the injection, accompanied by fever and malaise, lasting twelve hours. The injection was done in the lateral abdominal wall.

In the second case, a nurse in another family, the antitoxin was introduced into the upper and outer aspect of the left arm; and in five days a very fine scarlet papular rash appeared, attended with tremendous itching, and extending from the shoulder to the elbow. It looked, as the nurse remarked, like a limited area of scarlatina.

In the third patient, a male attendant in still another family, the injection was done by the patient in the calf of the leg, and in five days was followed by an urticarial eruption about the seat of the puncture.

There were no systemic symptoms in either of the two latter cases. While such unpleasant features should certainly not lead us to sacrifice the advantages to be gained by antitoxin, yet they may be worthy of mention, as in the prospectus issued by Dr. Gibier it is stated that there is "no local reaction" following its injection. On the other hand, in four cases of diphtheria where twenty-five cubic centimetres of antitoxin were injected as a curative remedy, no eruption or untoward symptoms have been noted. The syringe used is the one recommended, and furnished, I believe, by Gibier. It holds twenty-five cubic centimetres, and was made thoroughly aseptic in every instance. This syringe has a plunger, and is of metal and glass graduated. The four diphtheritic cases improved wonderfully, both as regard general symptoms and local lesions, after the use of antitoxin, which was employed on the first day of the disease, and the diagnosis verified afterwards bacteriologically by Dr. H. C. Ernst in each case. In a boy, seven years old, albuminuria and partial paralysis persisted some weeks notwithstanding the antitoxin. This boy's sister was apparently not more critically ill than he at the outset; but having no antitoxin on hand then, I sent her to a hospital, where she died on the twelfth day of general exhaustion due to the toxic infection, not having been treated with antitoxin at any period of her sickness.

The baby before mentioned, immunized with five cubic centimetres of antitoxin, had been lying all day in the same bed with a fully-developed case of diphtheria, and yet has shown no symptoms of the disease — neither have the other patients receiving prophylactic doses, although being adults this is not particularly surprising.

KENELM WINSLOW, M.D.

P. S. (December 31). Since writing the above I have had two cases of very extensive and annoying urticaria occurring in diphtheria patients innoculated seven days previous to this eruption with the New York Pasteur laboratory preparation of antitoxin. Can it be any fault of this special preparation? Is it due to the camphor contained therein and used to preserve the serum? K. W.

## SERUM THERAPY IN PARIS.

HÔPITAL DES ENFANTS MALADES,
PARIS, Dec. 18, 1894.

MR. EDITOR: — It may be of interest to your readers to learn that out of a series of 118 cases of diphtheria treated in the service of Dr. Chaillou since November 17th by means of the Roux serum, there has been a mortality of ten only, or less than ten per cent. Of these cases four should be excluded as they were of the foudroyant nature and practically moribund on admission. No auxilliary treatment is given beyond lavage of the nares. I observe that tracheotomy is seldom resorted to, intubation being given the preference. Diphtheritic paralysis as sequela is also a rare phenomenon. A. GASTON ROETH, M.D.

## A CHARACTERISTIC LETTER FROM DR. HOLMES.

BOSTON, December 23, 1894.

MR. EDITOR: — A gentleman, late of Houston, Texas, Fiquet by name, a graduate of Harvard University and Law School, failing in health, went into the business of breeding fancy cattle. At the outset, he intelligently determined, if there were a method of producing sex at will, that he would discover it. He claimed, finally, that he had done so, experimented largely, and, according to his own showing, successfully. After a time he had accumulated a large mass of printed and manuscript matter, in which he gave a detailed history of his experiments in the

direction in question. This printed and written evidence of his success, Mr. Fiquet sent to Dr. Holmes, with the request that he would bring it to the attention of physicians.

At that time I was a member of the editorial staff of the JOURNAL. The matter from Fiquet was therefore turned over to me in order that I might condense it into an editorial. I did so, and then sent my result to Dr. Holmes for his approval, which he sent me in the following thoroughly characteristic letter:

296 Beacon St., May 7, 1880.

MY DEAR DOCTOR: — I have carefully read your abstract, with which I am very much pleased, and made a few corrections, or at least suggestions, in pencil.

On the whole I think I would *not* print the passages marked in the letter of Mr. Fiquet you send me. Some will think they give too theoretical an aspect to what is a matter chiefly at present of practical experimentation.

I shall be happy to look over the proofs if you would like to have me, but I do not wish to have my name mixed up with the taurine and vaccine gallantries.

Yours very truly,

O. W. HOLMES.

When you have done with the letters, you may, if you please, send them all back to me.

Soon after discovering this letter among my papers, I met Dr. Holmes for the last time. During our conversation I asked him if he remembered the Fiquet matter, and found he had entirely forgotten it. Recalling to his mind the editorial and his note to me, I repeated to him the paragraph anent his wish to remain unmentioned. He laughed as heartily as many will who now read it for the first time.

The editorial was entitled "Production of Sex at Will," and was published in the JOURNAL for May 13, 1880.

Yours truly,

HAMILTON OSGOOD, M.D.

## THE TREND OF IMPROVEMENT IN THE PHYSICIAN BY REASON OF INCREASING COMPETITION; OR, THE HOSPITAL PHYSICIAN *VS.* THE INDEPENDENT PRACTITIONER.

PHILADELPHIA, December 20, 1894.

MR. EDITOR: — The very admirable and wholesome article by Dr. Schaefer in the *Boston Medical and Surgical Journal* of November 22d, on commercialism or tradesmanship in medicine, suggests two or three rather obvious corollary thoughts which I beg leave to present with no undue elaboration.

Dr. Schaefer seems to cry aloud, with a very bitter cry (in which we deeply sympathize), he having the commercial atmosphere of the West thick upon him. Those of us who, trained in the East, have not experienced this confusing effect upon scientific and ethical aspirations, thus exercised, will feel as keenly as he does, and deplore deeply, what seems to be an overmastering influence. True as is all he says, yet there are other results to be looked for from the conditions enumerated, and one is that keenness in competition compels our young medical men to strive for broader and deeper knowledge, and, not content with undergraduate teaching, to reach out for that special training which is only to be had by living in and doing the work of hospitals — first, by their spending years of earnest toil in dispensary services, examining and prescribing for the hordes there applying for advice, and finally seeking and getting, in proportion to their abilities, controlling positions on the working staff of those magnificent aggregations of clinical material and beneficent asylums, the large general and special hospitals. Thus, and thus only, can the highest scientific medical work be done; thus only can the highest qualities of knowledge and practical competency be perfected — in which the public is the chief gainer.

Again, in specialism, and in strict specialism only, can the most thorough knowledge be attained of the disorders and treatment of particular organs. To be sure, the man of general, all-round attainments will forever be of the utmost value in the formation of just estimates of the larger and wider considerations of such accidents as environment and differing social planes, occupations, temperaments, and varying degrees of vitality and disease tendencies. But here, indeed, is a specialism of its own, and of the very highest type, too, demanding a breadth of mind and heart far in advance of the narrower pursuits of ophthalmology or gynecology. And it is through refinements such as these that the giants of our profession exert their best influences and gain highest rewards of honors, love and gold.

This striving and competing, too, beats down the men feeble in mind or conscience, or both, and they go elsewhere and mayhap descend to lower methods, more commercial and tradesman-like. But these are only the incidental secondary effects of modern influences very conspicuous indeed to the layman and caviller.

The real balance of power, however, is the *Public*. So soon as they learn (and this process seems well underway) to realize the advantages to them of correctly, or even fairly, estimating the comparative competencies of competing men and cease to be taken in by noisy chaffery or pseudo-sciences, then their salvation will be greatly enhanced. They estimate a lawyer far more correctly than a doctor; a clergyman least well.

I fear no such calamities as Dr. Schaefer threatens. The objectionable aspects of medical practice often enough conspicuously obscure those imperishable, underlying, ethical elements inherent in the medical profession.

Very truly yours,

J. MADISON TAYLOR, M.D.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, DECEMBER 22, 1894.

| Cities. | Estimated population. | Reported deaths in each. | Deaths under five years. | Percentage of deaths from | | | | |
|---|---|---|---|---|---|---|---|---|
| | | | | Infectious diseases. | Acute lung diseases. | Typhoid fever. | Diphtheria and croup. | Scarlet fever. |

Deaths reported 2,406: under five years of age 770; principal infectious diseases (small-pox, measles, diphtheria and croup,

diarrheal diseases, whooping-cough, erysipelas and fevers) 351, acute lung diseases 373, consumption 287, diphtheria and croup 178, typhoid fever 45, scarlet fever 38, diarrheal diseases 36, whooping-cough 16, erysipelas 10, measles 6, small-pox 3, malarial fever 3.

From diarrheal diseases New York 12, Philadelphia and Cincinnati 4 each, Providence, Fall River and New Bedford 3 each, Cleveland 2, Brooklyn, Washington and Worcester 1 each. From whooping-cough Brooklyn 6, New York and Boston 3 each, Cincinnati, Fall River, Cambridge and Quincy 1 each From erysipelas New York 5, Boston 2, Brooklyn, Nashville and Lowell 1 each. From measles New York 4, Brooklyn and Cincinnati 1 each. From small-pox Philadelphia 2, New York 1. From malarial fever Brooklyn 2, New York 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,458,442, for the week ending December 15th, the death-rate was 19.7. Deaths reported 3,959; acute diseases of the re-piratory organs (London) 358, measles 154, diphtheria 87, whooping-cough 57, fever 55, scarlet fever 35, diarrhea 35, small-pox (Birmingham 3, Birkenhead and Halifax 1 each) 5.

The death-rate ranged from 11.8 in West Ham to 28.9 in Oldham; Birmingham 19.3, Bradford 25.1, Croydon 13.5, Gateshead 22.3, Hull 16.9, Leeds 25.9, Leicester 21.2, Liverpool 24.6, London 18.6, Manchester 20.3, Newcastle-on-Tyne 20.9, Nottingham 17.3, Portsmouth 19.2, Sheffield 21 4.

## METEOROLOGICAL RECORD,

**For the week ending December 22d, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—**

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 22, 1894, TO DECEMBER 28, 1894.

Leave of absence for one month is granted FIRST-LIEUT. A. N. STARK, assistant surgeon, to take effect upon his return to Fort Sam Houston, Texas.

CAPTAIN JAMES D. GLENNAN, assistant surgeon, is relieved from duty at Fort Sill, Oklahoma Territory, and ordered to Fort Snelling, Minnesota, for duty at that post.

## HARVARD MEDICAL SCHOOL.

### EVENING LECTURES.

The next lecture will be given on Thursday evening, January 10th, at 8 o'clock, by Prof. J. C. White. Subject, "The Cutaneous Features of Tuberculosis, Syphilis and Leprosy." Physicians are cordially invited.

## SOCIETY NOTICES.

THE WARREN CLUB. – A regular meeting of the Club will be held at 225 Marlborough Street, on Tuesday evening, January 8th, at 8 o'clock.

Dr. E. S. Jack: "Intestinal Obstruction."

Dr. A. C. Jelly: "Early Signs of Mental Disorder."

W. E. PAUL, M.D., *Secretary*.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. – The annual meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday, January 7, 1895, at eight o'clock, P. M.

Dr. John Homans: "The Surgical Treatment of Uterine Fibroids."

Dr. E. O. Otis: "Some Methods of Chest Examinations Supplementary to Auscultation and Percussion."

Report of the Treasurer.

Election of officers.

JOHN T. BOWEN, M.D., *Secretary*.

## RECENT DEATHS.

SILAS ATHERTON HOLMAN, M.D., of York Harbor, Me., died December 24th. He was a graduate of the Harvard Medical School, class of 1855, and served as a surgeon during the Civil War.

HORACE O. DUNBAR, of Athol, died December 27th, aged forty-five years. He was a graduate of the Medical Department of the University of the City of New York.

## BOOKS AND PAMPHLETS RECEIVED.

New Instruments. By Seth Scott Bishop, M.D. Reprint. 1894.

An Address on Appendicitis. By J. William White, M.D. Reprint. 1894.

The Annual Statistics of Manufacturers of Massachusetts, Eighth Report, 1893.

Some Statistics of Diabetes Mellitus. By N. S. Davis, Jr., A.M., M.D. Reprint. 1894.

Some Meteorological Data. By Samuel A. Fisk, A.M., M.D., Denver, Col. Reprint. 1894.

Theatre Fire Catastrophes and their Prevention. By Wm. Paul Gerhard, C.E. Reprint.

Biennial Report of the Officers of the Brattleboro Retreat for the period ending June 30, 1894.

Twenty-fourth Annual Report of the Bureau of Statistics of Labor of Massachusetts, March, 1894.

Cauterization of the Nares and Accidents that may Follow. By E. Fletcher Ingals, A.M., M.D., Chicago. Reprint. 1894.

Symphyseotomy *versus* the Induction of Premature Labor. Uterine Fibroids. By Charles P. Noble, M.D., Philadelphia. Reprints. 1894.

Forty-second Annual Announcement of the Medical Department of the University of Vermont and State Agricultural College for the year 1895.

Military Medicine, Surgery and Hygiene; Notes on the Introduction of Tent Field Hospitals in War. By Col. B. J. D. Irwin, M.D. Reprint. 1894.

Sperminum-Poehl in chemischer, physiologischer und therapeutischer Beziehung. Von Dr. G. Bubis. St. Petersburg: Buchdruckerei von Wienecke. 1894.

Higher Education in Iowa. By Leonard F. Parker, Professor of History in Iowa College. Washington, D. C.: Bureau of Education, Circular of Information, No. 6. 1893.

Transactions of the Medical Society of the State of Pennsylvania at its Forty-fourth Annual Session held at Philadelphia, 1894. Vol. XXV. Philadelphia: Published by the Society. 1894.

Higher Education in Tennessee. By Lucius Salisbury Mernam, Ph.D., Instructor in Political Economy in Cornell University. Washington, D. C.: Bureau of Education, Circular of Information, No. 5. 1893.

The Pre-Tubercular and Pre-Bacillary Stages of Consumption. A Consideration of the Early Diagnostic Signs of Pulmonary Tuberculosis; A Plea for the Recognition of Premonitory Symptoms. By Charles Manly, A.M., M.D. Reprint. 1894.

Local Anesthetics and Cocaine Analgesia, their Uses and Limitations. By Thomas H. Manley, A.M., M.D., Member of the New York Academy of Medicine; the New York Pathological Society, etc. St. Louis: J. H. Chambers & Co. 1894.

Essentials of Chemistry and Toxicology for the Use of Students in Medicine. By R. A. Witthaus, A.M., M.D., Professor of Chemistry and Physics in the University of New York, etc. Twelfth edition. New York: William Wood & Co. 1894.

Dissections Illustrated, A Graphic Handbook for Students of Human Anatomy. By C. Gordon Brodie, F.R.C.S. In four parts. Part III, The Head, Neck and Thorax, with twenty colored plates. New York and London: Whittaker & Co. 1894.

New York Letters on Orthopedic Surgery. The Scope of Orthopedic Surgery. Tubercular Abscesses and their Treatment. Old and Neglected Deformities following Infantile Spinal Paralysis. The Use of Traction in the Treatment of Joint Diseases. By Stewart Leroy McCurdy, A.M., M.D., Pittsburgh, Pa. Reprints. 1894.

Medical Jurisprudence, Forensic Medicine and Toxicology. By R. A. Witthaus, A.M., M.D, Professor of Chemistry, Physics and Hygiene in the University of the City of New York, etc.: and Tracy C. Becker, A.B., LL.B., Professor of Criminal Law and Medical Jurisprudence in the University of Buffalo. Volume II. New York: William Wood & Co. 1894.

# Lecture.

## TUMOR OF THE CEREBELLUM, WITH BULIMIA AND RECURRENT APOPLECTIFORM SEIZURES.[1]

BY J. T. ESKRIDGE, M.D., DENVER, COLO.,

*Professor of Nervous and Mental Diseases and Medical Jurisprudence in the Medical Department of the University of Colorado; Neurologist to the Arapahoe County and St. Luke's Hospitals.*

THE case of the patient who lies before us to-day in a stuporous and almost completely unconscious state presents many features of interest to which I wish to direct your attention. The history is as follows:

A. A., age twenty-six, male, married, born in Sweden, laborer by occupation, was admitted to the nervous wards of this hospital, in a stupid and confused condition, May 2, 1894. The stupor gradually deepened, and by noon the next day, the time of my first visit to the hospital after his admission, he was nearly comatose. His breathing was slow, and, as a rule, noiseless, but occasionally it was slightly stertorous with periods of intermission lasting ten or fifteen seconds. On the day of admission to the hospital, the temperature was 98°, pulse 100 and respiration 24. At the time of my first seeing him the temperature was 99° in each axilla, pulse 57, and respiration 16. He vomited on entering the hospital, and once during the next morning. The body showed evidences of considerable emaciation. There was slight stiffness of the posterior cervical muscles, with some retraction of the head. There was no apparent paralysis of any muscles. Whether there was any paresis, it was impossible to determine on account of the stupor. There was well-marked retraction of the abdomen. The knee-jerks were equal and decidedly increased. Ankle-clonus, plantar, cremaster and abdominal reflexes were absent. Reflexes of the extensor muscles of the forearms, biceps and triceps were slightly increased. Corneal reflexes, tested by touching the cornea with tip of finger: right, slight; left, scarcely perceptible. It was impossible to rouse him from the comatose condition by pricking his skin with the sharp points of an esthesiometer. Pricking the right leg caused slight movement of this leg, but irritating the left leg in the same manner gave rise to no response. Pressing firmly over the supra-orbital nerves produced no apparent effect. The pupils were reported by the resident physician to be small and equal in size on his admission to the hospital, but they had been widely dilated with atropine before I saw him. The ophthalmoscope revealed choked disk in each eye, and the nerves were best seen with + 5 D. The vessels over the optic disks were covered by exudate, and considerable hemorrhagic extravasation in the retinæ surrounding the disks was found. The veins were distended and tortuous; the arteries varied little from normal. Urine was normal in quantity, with a specific gravity of 1.015, and contained neither albumin nor sugar. One drachm of blue ointment was ordered to be rubbed in thrice daily.

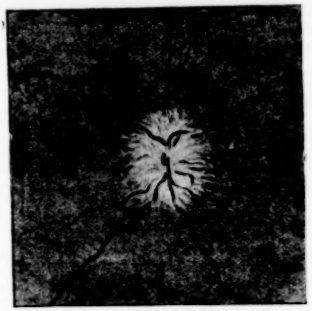
May 5th, two days later, the patient had regained consciousness and was able to give the following account of himself: His family history, so far as he could remember, was negative. He had no illness during childhood. He denied syphilis, but admitted illicit intercourse and occasional indulgence in alcohol. His first illness was three years ago, when he suffered from some acute gastric disorder, attended by pain in the stomach and vomiting, lasting about three weeks. After this attack, he was well until July, 1893, when he began to suffer from nausea, vomiting and "sick-headache." Headache was not constant until five weeks ago, but it recurred from time to time, the pain, principally in the frontal and occipital regions, getting worse and more persistent. During the five weeks previous to his coming to the hospital, he had a constant distress in the head, with occasional attacks of vomiting. The vomiting did not seem to be connected with taking food, and often occurred when the stomach was empty. Two weeks ago, his headache became so distressing, attended by frequent vomiting, that he was compelled to quit work and take to his bed. He was further incapacitated for work on account of difficulty in walking and standing, and increasing weakness.

On examination, May 5, 1894, he was able to stand with eyes open for a short time when the feet were placed close together, but his body swayed to the left and backwards. His gait on walking forwards was like that of a drunken man. His body swayed; his step was uncertain; and his feet were kept wide apart, but he did not raise them unduly high, neither did he seem to exert too great muscular effort as is observed in certain forms of ataxia. Walking backwards, even with the eyes open, was very difficult, and was performed with body leaning forwards, while he pushed the feet backwards. On closing the eyes and trying to stand with feet close together, or to walk forwards, he fell towards the left and backwards. He was unable to take a single step backwards while the eyes were closed, and an attempt to do so caused the body to plunge in the same direction towards which it swayed when he was trying to stand with closed eyes. Knee-jerks: right absent, both direct and reinforced; left direct, slight; reinforced, a little more pronounced. Ankle-clonus, plantar, cremaster and abdominal reflexes absent. Reflexes of extensors of forearms about normal; triceps lessened; biceps decidedly increased. Dynamometer: right, 96; left, 110. The tongue was protruded in the median line. The face was expressionless. There was no apparent paresis or paralysis of any muscles. The pupils were still widely dilated with atropine. All general sensory phenomena were apparently normal, with the possible exception of tactile sense on the tips of fingers, where it seemed less acute than is commonly found, as shown by the difficulty that he experienced in distinguishing two points of the esthesiometer; but this was attributed to his impaired mental vigor, as he could readily recognize the slightest contact of a feather on any portion of the body, including the finger tips. Hearing for watch: right, one-third of the normal distance; left, on contact. Hearing for tuning-fork better in the right ear. Smell and taste present, and about equally acute on the two sides. In the right eye V = counts fingers at ten feet; fields all narrowed, most on the nasal side; ophthalmoscopic changes were the same as observed two days before. In the left eye V = counts fingers at twelve feet; fields and changes in fundus and disc about the same as observed in the right eye. There was a well-marked internal squint of the left eye, with occasional twitching of the left internal rectus muscle. He was unable to turn the right eye outwards to the normal degree, and the external rectus of the left eye was weaker than that of the right. He failed in the attempt to turn either eye downwards, and the effort caused overaction of the left internal rectus. He succeeded in turning the eyes upwards, but only a little beyond the horizontal axis, and the effort to carry the eyes further upwards caused marked convergence of both eyes. All the external ocular muscles, except the internal recti were weakened. It was impossible to determine the condition of the intra-ocular muscles on account of the pupils having been dilated with atropine. The resident physician stated that the pupils were very small when the patient was brought to the hospital, and he had dilated them to make it possible for me, on my arrival, to make an ophthalmoscopic examination of the fundi of the eyes.

His headache soon lessened, vomiting ceased, appetite became ravenous, and he gained flesh. Soon after beginning the treatment, nearly all the eye muscles improved in power, but there remained an internal squint of the left eye. The pupils became very small as soon as the influence of the atropine had subsided, and dilated but little when the eyes were shaded. On June 5th, without any apparent cause, the temperature descended to 96.8° F. It had been normal, or only varied half a degree up to this time. June 16th, he had a severe headache and vomited once or twice; head pain complained of in frontal region. He

[1] A clinical lecture delivered at the Arapahoe County Hospital, November 3, 1894.

again became unconscious, and was for a few hours in a deeply comatose condition. The face was deeply congested and much darker than usual; respiration was intermittent, and pulse slow and labored. On the 18th he had regained consciousness; and at 9.30 P. M. he had a severe general convulsion, and remained in a profound stupor until 2 A. M. of the 19th. On the 20th he was totally blind, and suffered severely from headache. Again he became comatose; and remained so for two or three days, presenting symptoms similar to the previous attacks. June 25th he was conscious, and was able to see nearly as well as he could on admission; but vision gradually decreased, and by July 19th he was totally blind, and has remained so since. July 22d he had a severe convulsion at 5 P. M., lasting about ten minutes. The spasm was tonic in character, face very dark, head turned to right and somewhat retracted, pupils very small. July 25th hearing failing rapidly; by the latter part of August, he could hear only loud sounds, and was so deaf it was impossible to make him understand anything.



Bulimia, or excessive hunger, was a very prominent symptom from the early part of June to the middle of October. During this time it was the custom of the nurses to serve him with two or three times the quantity of food required for convalescents whose appetites could not be surpassed by laboring men in vigorous health. He would eat all that was given him, and complain to me at my visits that he was being starved. I have frequently seen the quantity of food served him, and observed him eat. He would consume, in a short space of time, ten or twelve large, thick slices of bread, with meat, butter and vegetables in proportion. He ate like a man half starved. Thirst has never been excessive. He gained greatly in weight notwithstanding occasional attacks of vomiting.

The mercurial inunctions on which he was placed soon after entering the hospital were continued alone for three or four weeks. He seemed to improve during the first two weeks, but after this improvement ceased. Early in June potassium iodide, in increasing doses, was given in addition to the inunctions. The mixed treatment was continued until he was getting 100 grains of potassium iodide thrice daily, but no benefit seemed to result. Then potassium iodide was given without mercury; but the result was negative, and he gradually lost ground. He has had no special medication during the last six weeks or more.

His morbid appetite began to lessen about two weeks ago. He still has attacks of vomiting, but does not complain of headache much. He has made no effort to stand for three months. He lies in a semi-comatose condition most of the time; and if he gets uncovered or one leg falls out of bed, he is indifferent and makes no effort to replace the covering or correct the position of his leg. Until two or three weeks ago, he notified the attendants when he desired the urinal or bed-pan, but since then, he has passed the contents of the bladder and bowels in bed without endeavoring to attract any attention. He had a severe convulsive seizure last night.

He is now deaf and blind. It is impossible to test the senses of smell and taste. Pricking a limb causes him to draw it up, and if the irritation is continued he will ask, "What is the matter, what do you want?" There is no paralysis of the muscles of the limbs. The functional integrity of the anal and visceral sphincters is preserved, and to the mental failure we must attribute his neglect of habits of cleanliness. The left side of the face seems paretic when he yawns, but the face is not drawn to the right when the muscles are at rest. The contour of the body is well preserved, and there is no emaciation or muscular wasting. The ophthalmoscope reveals the usual trophic changes that follow choked disk. There is well-marked convergence of the left eye, and moderate divergence of the right. The latter is observed to turn inwards at times on a line with the vertical axis, but the left never turns outward. The eyes are not observed to turn upwards or downwards. Whether he is able to move the eyes in these directions it is impossible to determine at this time. The pupils remain very small and do not dilate when shaded. There is no protrusion of the eye-balls.

The patient, whose history I have reported to you with results of examinations under two distinct circumstances, furnishes illustrations of difficulties in the problems of diagnosis. The first difficulty was encountered in trying to determine the nature of his trouble when I first saw him in a comatose state, and this, too, in the absence of any knowledge of his previous condition, or of the manner in which unconsciousness came on. The next was experienced in endeavoring to localize, with the additional aid of the meagre history and the consciousness of the patient, the lesion that I had diagnosticated during the state of coma.

Appearance of fundi, November 3, 1894.

### DIAGNOSIS DURING COMA.

If summoned to see a patient in a comatose condition, our first duty, after meeting any emergency that may seem obvious, is to make a diagnosis. Cardiac syncope; chloral, opium, alcohol and other poisons; uremia; epilepsy; hysteria; apoplectiform attacks occurring from cerebral congestion or from the cerebral state found in some cases of paretic dementia, "simple apoplexy" in the aged; embolism; thrombosis; hemorrhage; abscess; tumor; and inflammatory conditions of the brain, give rise to symptoms somewhat similar. If we are ignorant of the history of the patient and the mode of the development of the comatose state, we may in some cases find it difficult or impossible to arrive at a satisfactory conclusion.

I hope soon to be able to illustrate by cases many of the difficulties encountered in arriving at a satisfactory diagnosis in the apoplectic state. Fortunately, the patient before us presented one prominent symptom that enabled us at once to exclude most of the causes of coma above enumerated. This symptom was choked disk. It illustrates the value of an ophthalmoscopic examination in all cases of unconsciousness. Excluding organic brain lesions, there are three conditions that may give rise to choked disk. These are lead-poisoning, profound anemia and kidney disease. Headache, optic neuritis, convulsions and delirium followed by coma may be caused by lead-poisoning; but other obtrusive symptoms of saturnism, such as the blue line of the gums, the peculiar appearance of the patient, are present. Nothing that indicated lead-poisoning, not even convulsions nor delirium, was present in this case. The very high degree of swelling of the optic disks found in our patient, rarely, if ever, occurs from lead. When optic neuritis is due to anemia, the swelling is very much less than was found

in the patient whose case is under consideration, and the symptoms of anemia are pronounced. While the patient at the time of his admission to the hospital was emaciated, yet he did not present an anemic appearance. Kidney disease was excluded by the absence of albumin and tube casts in the urine.

The organic diseases of the brain — besides the acute inflammatory conditions, with considerable exudate or watery effusion — that may cause choked disks are tumor, abscess, and sometimes embolism. A normal or subnormal temperature would justify the exclusion of the acute inflammatory processes of the brain or its membranes, with a very few exceptions, the consideration of which is unnecessary for us at the present to discuss. The swelling of the optic disks following embolism is not as great as was found in this patient; and no source of an embolus, such as a cardiac murmur or a blood state, was found. Besides, embolism that has existed sufficiently long to produce choked disk would be attended with softening and probably with paralysis.

The diagnosis is narrowed down to abscess or tumor of the brain. Even with a reliable history, it is not always easy, and sometimes it is impossible, to make a positive diagnosis between tumor and chronic abscess of the brain. In about three-fourths of the cases of abscess, a source of the suppuration, such as chronic ear disease, infective states of the bones of the nose or skull, or suppuration in the lungs or elsewhere, will be found. In this case, tumor of the brain was diagnosticated on the presence of the enormous swelling found in the optic disks. It had attained a degree of intensity that is probably never reached in abscesses of the brain.

After the patient had regained consciousness and was able to give a fairly good history of his symptoms previous to his coming to the hospital, and after making a thorough examination under more favorable circumstances, nothing was found that leads me to change my diagnosis.

### LOCALIZATION.

Accepting the conclusion that this man is suffering from the presence of a tumor in his brain, let us proceed to analyze his symptoms with the view to localizing the growth. Exact localization of brain lesions is possible only when certain regions, whose functions are pretty definitely known, are involved. These include the cortical motor areas, the cuneus or the median surface of the occipital lobe, a portion of the temporo-sphenoidal lobe, more especially the left side, the internal capsule, crus, pons, medulla, and the regions at the base of the brain that contain certain cranial nerves. Lesions in the frontal, parietal and outer portion of the occipital lobes, or in the centrum ovale or cerebellum are sometimes very difficult to localize. We must bear in mind that a large tumor may have its seat in a portion of the brain, destruction of which gives rise to no obtrusive symptoms, and by the pressure and other effects of the growth, adjacent regions whose functions are known, may be seriously affected, causing symptoms of a definite character and leading the diagnostician to err in localizing the morbid process in the portion of the brain which has been indirectly affected by it. I have known tumors situated in the frontal and parietal lobes, and in the centrum ovale to cause hemiparesis without any extension of the growth to the motor region.

In the case of the patient before us we can exclude the temporo-sphenoidal lobe, the visual centre of the occipital lobe, and the motor regions of the cortex, because the functions of these portions of the brain have not been affected as they would be were any of them the seat of a tumor. From the fact that this man's deafness is bilateral and the motor cranial nerves are not paralyzed, we may exclude the base of the cerebrum from being the seat of the growth. A tumor in one of the frontal or parietal lobes, or in the centrum ovale, would not give rise to bilateral deafness, and a growth in each hemisphere is too rare to merit consideration in this case. The probabilities are that the tumor in this man is situated in the neighborhood of the corpora quadrigemina or in the cerebellum. Lesions involving the former are usually attended by headache, vomiting, optic neuritis and ataxia — symptoms very prominent in this patient. A tumor in the centrum ovale of one hemisphere, by indirect pressure upon the corpora quadrigemina may cause a staggering gait that is almost identical with the titubation caused by a growth in the cerebellum, but the symptoms would be much more prominent on one side than on the other. A few months ago a man, about forty years old, died in this hospital from a tumor of the brain. During life he presented many symptoms, especially the gait, optic neuritis, occasional headache, etc., of a cerebellar growth. There was no unilateral symptom, but simply inability to stand during a number of months preceding his death, because of muscular rigidity and loss of the power of co-ordination. There were no paralysis, but a weakening of all the muscles of the limbs. He was blind, but hearing was not affected. On his admission to the hospital the gait and the tendency to fall to the left and backwards made me suspect a growth in the cerebellum; but as the disease advanced and the nerves whose nuclei of origin are in the floor of the fourth ventricle did not become affected, I was lead to locate the lesion anterior to the pons. The autopsy revealed an enormous growth involving the posterior portion of the corpus callosum extending well into the centrum ovale of each hemisphere and exerting pressure directly on the corpora quadrigemina. The symptoms of a growth in these bodies would be bilateral in character, but for the tumor to extend sufficiently downwards to destroy the nuclei of origin of the auditory nerves, the nuclei of the third cranial nerves would be rendered functionless before such a result could in all probability take place. I think we are justified in locating the lesion in this case in the cerebellum, affecting its middle lobe or vermes, and probably extending a little further to the left side than to the right. I only suspect that the tumor has invaded the cerebellum a little more to the left of the median line than to the right, because the tendency has been, when he has been able to be on his feet to fall to the left and backwards, although numerous cases of tumor of the cerebellum are on record where the body has swayed from the side in which the growth was situated.

We will now consider the most prominent symptoms found in this patient's case, and see if they may be accounted for by a growth in the cerebellum. Headache, vomiting, optic neuritis, blindness, convulsions, unsteadiness of gait, and often deafness, are the usual symptoms of tumor of the cerebellum involving the middle lobe.

The recurrent attacks of coma attended with venous congestion of the face, slow pulse and respiration, may be accounted for by pressure on the lateral and occipital sinuses into which the veins of Galen empty. The latter receives the blood from the walls of the ventricles, the choroid plexuses and corpus callosum. Any sudden increase of pressure below the tentorium, as would likely result from a spreading tumor in the cerebellum, might give rise to attacks of coma, the circulation becoming re-established and consciousness returning as the parts adapt themselves to the changed conditions. Sometimes the congestion is so great that life can no longer be maintained, and sudden death may thus take place in growths of this portion of the brain.

The mental failure in this case, as occurs in many others of like nature, is also probably due to disturbed circulation.

The paresis of the left side of the face which has recently developed, slight difference in the knee-jerks of the two sides, with less acute sensory functions of the left side, may be explained by assuming that the tumor presses a little more on the left side of the pons than on the right.

How are we to explain the persistent small pupil in a man totally blind, the convergence of the left eye, slight divergence of the right and the limitation of the upward and downward movements of the eyes with a tendency to convergence of both eyes when he attempts to move the eyes upwards or downwards? Most of the nuclei which give origin to the nerve fibres that supply the muscles involved in these movements are situated beneath the floor of the aqueduct of Sylvius; and as we have seen that the veins from this portion of the brain are probably kept engorged from the interference with the circulation in these veins caused by pressure on the occipital and lateral sinuses, it is probable that these nuclei are in a constant state of irritation, "irritable weakness." In health, extreme convergence of the eyes is attended with contraction of the pupils. Each internal and external rectus of the eye is supplied by nerve fibres that are innervated by two separate and distinct nuclei, one acting when both internal recti contract and cause convergence of the eyes, the other when both eyes turn to the right or left. Or the mechanism may be explained by supposing one set of nuclei for each muscle, but so arranged that the internal recti may act in harmony with each other, or those of one internal rectus may act in conjunction with those of external rectus of the other eye. As the internal recti muscles are the most powerful muscles of the eye, convergence of the eyes would naturally be the result of ineffectual efforts to move the eyes upwards or downwards.

Bulimia may be caused by disease of the brain, stomach or some other organ. Increased thirst, with diabetes insipidus or mellitus, is more common in irritation of the floor of the fourth ventricle, than increased sensation of hunger, but as bulimia has been found in cases of diabetes mellitus, it is probable that there is a centre in the fourth ventricle, irritation of which gives rise to a morbid sensation of hunger. It must be remembered that this man has suffered from chronic gastric disorder attended with severe pain in the stomach. The autopsy may reveal adhesions of the stomach to adjacent structures in such a manner as to prevent the walls of the organ from collapsing when empty. Ord cites two such cases, in both of which bulimia was a well-marked symptom.[2]

The prognosis of this patient's condition is utterly hopeless. The anti-syphilitic medication, which was resorted to in his case, has failed to arrest the progress of the disease, and surgical interference in tumor of the cerebellum, so far, has afforded but little beyond an ante-mortem examination of this portion of the brain, except in a few cases, in which pain has been relieved, and in two or three others, where life has been prolonged, the patient remaining blind.

### SUBSEQUENT HISTORY.

The patient gradually became more stuporous; he had general convulsive movements on two or three occasions; irritable stomach, with vomiting of nearly everything taken into jt, became a well-marked feature of the case; and finally he passed into a deep comatose condition, with pronounced cyanosis of the face, and died December 1, 1894, about four weeks after the lecture was delivered on his case.

*Autopsy.* — The body was placed in a cool place immediately after death and the examination was made by Dr. McClannahan and myself a few hours later. The brain and the organs in the abdominal cavity were the only parts investigated.

The external surface of the dura presented a normal appearance, but over the region of the cerebellum this membrane was quite tense and bulged on removal of the bone. On removing the brain from the base of the skull the infundibulum was torn across, leaving the pituitary body *in situ*. The canal in the infundibulum was greatly dilated, and through it three or four ounces of a straw-colored, watery fluid escaped from the ventricles. After exposing and examining the entire external surface of the brain, and the medial surfaces of the hemispheres of the cerebrum, no lesions were found on these parts. The vessels and nerves presented a normal appearance. On opening into the lateral ventricles they were found enormously distended but empty, as the fluid which they had contained escaped by the third ventricle and the infundibulum. No other evidence of disease was found in any part of the cerebrum. On exposing the upper surface of the cerebellum by removing the occipital lobes a growth was found in the middle lobe, principally in the anterior portion. On the left side of this lobe the tumor extended back to nearly the centre, but on the right side it affected only the anterior portion. The three peduncles of the cerebellum were involved by the tumor on the left side, and the middle and superior ones on the right. The growth projected forward of the cerebellum and infiltrated the structures that form the upper and lateral boundaries of the aqueduct of Sylvius and involved to a slight extent the corpora quadrigemina. Pressure was exerted on the floor of the fourth ventricle and on the floor of the aqueduct of Sylvius and on the veins of these parts and the adjacent sinuses, thus accounting for the accumulation of the fluid which was found in the lateral ventricles.

The organs in the abdominal cavity presented no abnormal condition. The stomach was carefully examined, but no cause for the condition of bulimia was found.

The cerebellar growth, which was soft and measured one and one-half inches from before backward and one inch at its widest part, was given to Dr. E. R. Axtell, pathologist to the hospital, and his report is as follows:

"To the naked eye the tumor mass is soft, and looks somewhat like brain tissue. It is more or less rounded, and is fairly sharply defined from the surrounding tissue which accompanies it. In color it is a dull, reddish pink, with no glistening white capsule nor bands of fibrous tissue running through it. Here and there in the mass are a few small red and brown spots looking like hemorrhagic areas.

"Sections of the tumor, made in all diameters, show that the mass is composed in part of small, round cells not

[2] British Medical Journal, June, 1889.

arranged in any special manner; here and there in the mass, but generally toward the area of normal tissue, the cells becoming definitely spindle-shaped, of large size, showing the formation of new connective tissue. The mass is nowhere exceedingly vascular, but small vessels can be seen forming in the spindled-celled area, and even in the mass of round cells.

"In the area of small, round cells there are a few patches of extravasated blood, but there is none in the area of spindle cells. The vessels about the mass contained blood, but gave no evidence of an endarteritis obliterans. Sections stained for the bacillus of tubercle failed to show any bacilli under a Leitz one-twelfth. No section showed any felted mass of fibrils, as is seen in a glio-sarcoma. The spindle-cells infiltrated the adjoining tissue without any definite capsule being formed.

"Diagnosis: mixed sarcoma of the small round and large spindle-cell form."

### RAPE.[1]

BY FRANCIS W. ANTHONY, M.D., BRADFORD, MASS.,
*Surgeon to Haverhill City Hospital.*

I SHALL ask your attention this afternoon to the subject of Rape — a medico-legal subject of so many branches and far-reaching roots that I can only hope to introduce it to your notice, trusting that its consideration may be not without value, even to the general practitioner.

It is difficult in preparing a paper of this sort from notes collected for several months in the intervals of a busy professional life, to credit all the authorities consulted; and, in imitation of our Newburyport friend who put at the close of his book *all* the punctuation marks, that the printer might distribute them as he saw fit, I wish here to acknowledge my obligation to Taylor, Briard, Tidy, Tardieu, Brouardel, Casper, Chaudé, Sajous and Wood; to R. von Kraft-Ebing and Chaddock; to Tyng, Metcalf, Pickering, Gray, Allen, Lathrop, Brown and Keller, requesting them to insert the quotation marks, if, in writing, I have omitted to place them. I wish also to acknowledge courtesies from Dr. F. W. Draper, medical examiner for Suffolk County; Dr. J. F. Croston, medical examiner for Essex County; Dr. E. S. Wood, expert of the Harvard Medical School, who kindly sent me the advance sheets of an article to be published this year on seminal stains; to Francis H. Pearl of the law firm of Abbott & Pearl, for the use of his medical library under his advice, and to District Attorney W. H. Moody, for privileges granted me.

The common form of definition declares rape to be the having of unlawful carnal knowledge by a man of a woman forcibly and against her will. The statutory term differs slightly, "Did not consent," being there used. A Massachusetts judge has decided that the two expressions are identical in meaning. A definition founded on the statutory term would be — "Rape is the having of unlawful carnal knowledge by a man of a woman, forcibly, where she does not consent," thus covering the case where a man by force has connection with a woman, the latter being asleep or drunk, said connection being therefore without her consent, though possibly by no means against her will.

The Public Statutes declare (Chap. 202, Sect. 27) that "whoever ravishes and carnally knows a female of the age of ten years or more by force and against her will, or unlawfully and carnally knows and abuses a female child under the age of ten years, shall be punished by imprisonment in the State Prison for life, or for any term of years"; and in Sect. 28, "That whoever assaults a female with intent to commit rape, shall be punished by imprisonment in State Prison for life, or for any term of years, or by a fine not exceeding $1,000, and imprisonment in jail not exceeding three years. Laws of 1888, Chap. 135, say, in substance, that an armed housebreaker whose intent is rape, whether assault is actually made or not, shall be punished by imprisonment in State Prison for life, or for any term of years not less than ten. In 1888 the age of consent was raised to fourteen; in 1893 this was again raised to sixteen.

In our country rape is also an offence against the common law.

Going back to periods remote — in the laws of Adelstone mentioned by Bracton, the crime of rape was punished by loss of life. As years went on this was considered too severe a punishment, and castration was substituted; while in the time of Henry VIII, this was replaced by loss of the eyes, unless the woman offended was single and so pleased by the experience that she elected the offender her husband, and the latter consented to assume the relation. In the time of Edward I, the age of consent was twelve years; the penalty for rape, two years imprisonment or a fine. When Elizabeth held sway, a man violating a female child under ten years of age was declared a felon, and compelled to suffer without allowance of clergy.

To-day, to constitute a rape the man must have physical capacity — although lack of this does not debar an indictment for attempt to rape — the will, in the eye of the law, being taken for the deed. In England and in North Carolina a boy under fourteen is conclusively presumed to be incapable, whatever the real facts. In general, in this country this establishes only a *prima facie* case, which actual testimony to the contrary may overthrow. Old age, even extreme old age, does not imply incapacity. In fact we shall see later that, in many instances, the fact of old age suggests the truthfulness of a charge of rape. Suffice it to say, for the present, that a man of ninety-two has been known to be the father of a child by his wife aged seventeen.

Absence of testicles in the scrotum is not a sufficient plea to set up against a charge of rape; for it is known that these crypsorchides are not only potent, they may be prolific.

As puberty in the male is not essential, so, also, the same is true in the female in case of rape. The offence may be committed against an unchaste woman or even a common prostitute, but want of chastity may, within certain recognized limits, be shown as rendering it more probable that the woman consented. Still, as decided by Morton (Judge) in the case of the Commonwealth *vs.* Thomas Harris: "In a prosecution for rape evidence of *particular* instances of unchastity on the part of the woman with persons other than the defendant is inadmissible, while her character may be impeached by *general* evidence of her reputation." An interesting question might arise in this connection: Are seminal stains found on the clothing of the woman the result of this rape, or of old cohabitation?

A husband cannot be found guilty of rape though he

[1] A paper read before the Haverhill Medical Club.

force his newly wedded wife to the consummation of the act without her consent and against her will; but if a husband be present abetting another man who forces said husband's wife, he is held the same as the principal in the offence. It was decided in the so-called "Methuen case," Commonwealth *vs.* Peter Scannel, that an indictment for rape need not allege that the defendant was over fourteen. The same decision practically was given in the case of the Commonwealth *vs.* Patrick Fogerty and others, in which case was also emphasized the principle that the husband assisting in a rape is chargeable as a principal. The audacity of defending a rape fiend on the ground *not* that the abused party *was* his wife, but that the indictment did not state that she was *not* his wife, strikes me as something tremendous, and I can only admire the calm tone of the judicial finding that ends with "Defendant's exceptions over-ruled" without adding a warrant for his lawyer for contempt of the capacity of the judge's mind.

A woman with less intellect than is required to make a contract may consent to carnal connection which, by the way, has been legally defined thus: "Carnal knowledge is sexual bodily connection," (Commonwealth *vs.* Charles N. Squires, 1867, Gray, J.). So that this carnal connection will not be rape; but if so idiotic as to be absolutely incapable of consent or dissent, and the man does not suppose he has her consent — note the loophole thus afforded — the connection is rape. From this it follows that the medical testimony as to the mental capacity of the woman in the case may affect the result of the trial; but if mental capacity is not shown, and even if rape be not proven, the defendant is not sure to escape; for it was decided in 1841, Commonwealth *vs.* Simon Fischblatt, that in an indictment for assault with intent to ravish, if "not guilty" be decided regarding the rape, "guilty of assault" may still be held, if force be proved.

Later will be considered the evidences of force from the physician's outlook.

The degree of force necessary to make an assault of this nature a rape, is interesting to note. Formerly emission was to be proved; later, penetration; but one decision maintains that an attempt to rape becomes a rape if the generative organs touch, for the outrage is not a threatened pregnancy or even the loss of the hymen, but the violence done the feelings.

It has been held in New York, that resistance on the part of the woman must be up to the point of being overpowered by actual force, by loss of strength to resist, from the number of persons making resistance dangerous or absolutely useless, or from dread or fear of death; — better judicial opinions do not endorse this view, but maintain that resistance must be made in good faith and not in mere pretence. In the case of the Commonwealth *vs.* Michael McDonnell (Pitman, J.), it was decided that the act must have been without consent on the woman's part; the defendant must have used sufficient force to have accomplished his purpose; that the degree of resistance was frequently essential in determining whether the want of consent was real, but that there was no rule of law requiring a jury to be satisfied that the woman, according to their measure of her strength, used all the physical force in opposition of which she was capable. The degree of resistance having then a distinct value in evidence, the methods of measuring this by a physician will be again referred to.

It was decided (Commonwealth *vs.* Patrick Fogerty and others) that an indictment for rape implies *force*, that is, it alleges that the defendant did, violently and against her will, feloniously ravish and carnally know the woman.

If the woman after the alleged offence excuses or forgives the defendant, still he can be convicted. This was decided in the case, Commonwealth *vs.* Edward Slattery (Allen, J.), in which it was shown that the defendant invited a young lady to ride, drove through some woods, got her to alight and ravished her; that then she re-entered the carriage, conversed on the way home, permitted him to assist her from the carriage; that on the way home she made no complaint, but did request marriage, and when this was refused, stated that if this refusal was persisted in she would "tell his folks." Despite the fact that to a degree she condoned the offence, it was held he could be convicted.

No rape can be maintained if consent is given before penetration or at least contact; but it must be borne in mind that consent given through fear is not consent.

The question has arisen how far ether and chloroform could be used and have the power of resistance overcome, the former drug having been used in a case in Pennsylvania, the latter in Ohio. It has been held that "If the woman had the capacity to hear, feel and remember, and a capacity to speak and forcibly resist, but the inclination to do so was lost, the will overcome by the action of the anesthetic either operating on the will faculty, the judgment and reflective faculties, or sexual emotions so that the mind was thereby incapable of fairly comprehending the nature and consequences of sexual intercourse, and the defendant, knowing these facts, had unlawful carnal knowledge of her forcibly, that would be a rape; and it would in such a case be wholly immaterial whether the entire mind was disordered and overthrown, or only such faculties thereof as are thereby rendered incapable of having just conceptions, and drawing therefrom correct conclusions in relation to the alleged rape."

The practical question may then arise to us as physicians, when, in the course of advancing anesthesia, is reached the point thus indicated? As we all know, the allegations of rape in dentists' offices are usually due to false ideas aroused by the anesthetic, but cases are on record where the dentist has been convicted.

Since hypnotism became better known and more practised, the question has been raised, Can a woman be ravished without her knowledge during hypnotic sleep? Brouardel says, "Only under favoring conditions." "If a man who is agreeable to the somnambulist offers suggestions to her which are acceptable or of an indifferent character and not offensive, she submits herself to them; but if the suggestions are revolting to her personal affections or her natural instincts, she opposes to them a resistance which is almost insuperable." Others think that a woman can be ravished during hypnotic sleep without the above-mentioned conditions. The question may be said to be an open one. French medical experts, as a rule, maintain that rape during hypnotic sleep is possible; but Taylor says that they forget "Non omnes dormiunt quae clausos habent oculos."

There is dispute also whether, barring cases where unconsciousness exists from fear, natural infirmity, the use of narcotics, liquors, anesthetics or hypnotism, rape could be accomplished. Taylor says that, barring the

above conditions and setting aside infants, idiots, lunatics, weak, delicate or aged women, it does not appear probable that intercourse could be accomplished against the consent of a healthy adult.

The exceptions are so numerous and broad that the statement seems to have an equivalent in this one — a man attempting rape *might* find himself overmatched in strength.

That a woman can be raped in natural sleep seems almost incredible. Casper relates the case of a married woman who alleged that while asleep she had been raped. In her deposition she admitted that she was conscious that some one was lying upon her, and that she asked who it was, showing that she had some doubts whether her husband was the party addressed. It would seem as though, except possibly in the case of substitution for a bridegroom during the early days of the honeymoon, something unfamiliar in physique or gesture might be detected by a woman awakened from a sleep; that she should sleep through such an experience seems incredible. [Since writing the above, credible evidence has been presented to me that in a woman not a virgin rape might be possible during sleep.]

During syncope rape could undoubtedly be committed without the knowledge of the victim.

The frequency of rape or attempts at rape may surprise some of you. Statistics show that in France in 1851 the rapes or attempts to rape upon adults, were 242; upon children, 615; total, 857. In 1861, upon adults, 217; children, 695; total, 912. In 1875, upon adults, 140; children, 813; total, 953. From 1851 to 1875 inclusive, the year furnishing the largest number of assaults of this nature was 1866, when the figures read, upon adults, 160; upon children, 883; total, 1,043. The whole number of such cases on record in the period mentioned, 1851 to 1875, inclusive, is, upon adults, 4,360; upon children, 17,657; grand total, 22,017.

The time of year seems well fixed when these assaults are most numerous; for example, in a series of about 800 cases covering a period of three years, statistics show that in the quarter including May, June and July, 293 cases occurred; August, September and October, 205; February, March, April, 171; November, December, January, 139. Another series from 1858 to 1869 gives a similar result; a closer examination discloses that *May* is the month in which rapes are most frequent, and that this is true, not only in France, but the world over as far as can be ascertained.

As regards the age of the victim: in 632 French cases, Tardieu states that 9 were over twenty; between fifteen and twenty, 84; between thirteen and fifteen, 90; under thirteen, 435; age not stated, 14. Old age is, however, by no means exempt. The youngest case reported is one reported by Dr. Brady, and cited by Taylor, the victim being nine months; one is upon record upon a child of eighteen months, and another of two years.

In case of an alleged rape it may become the duty of the attending physician to note certain facts coming fully as much in the line of the work of the police, who may be untrained observers. It is safe to say that here, as in a case of murder, nothing is of too little value to note, preferably in writing. The time called and time of arrival should be noticed, and, for obvious reasons, an early opportunity taken to compare your watch with standard time. Your examination of the garments of the victim, particularly of the shirt, underpetticoat and drawers should be thorough; if an opportunity is afforded, examine also the shirt and drawers of the male charged with the offence. Note the location and size of all stains, their odor, and degree of apparent freshness; all tears of garments, location and extent. If a bed figures in the alleged assault, examine its coverings or draperies, and note, not only stains as above, but tears or disarrangement; these, with the location of stains, may show the degree of resistance. On male attire the stains will of course be looked for more in front; on female attire either on front or back, sometimes on both. The importance of thorough examination was impressed upon me by District Attorney Moody, who reminded me of a case in New York or its immediate vicinity where a man was connected with an assault followed by murder, by the microscopic examination of the dirt under his finger-nails which disclosed vaginal epithelium.

The story of the victim is, of course, to be heard — simply as a story. She may be after blackmail; she may be self-deceived, insane or coached by others. If a child, the story of the mother or immediate relatives may be heard with the same caution. Mothers have been deceived by an innocent discharge, scrofulous, or due to oxyuris vermicularis, or masturbation. On the other hand, we must remember a child having such a discharge may be raped.

"Bearing in mind that medical evidence is seldom more than corroborative, but as important in false charges as true ones," says Taylor, "we examine the alleged victim for marks of violence about the genitals, stains of spermatic fluid which may be on the hair of the genitalia, stains on clothing as referred to above. If the case is alleged to be fresh, obtaining specimens of the vaginal mucus for further examination as to the presence of spermatozoa; if the case be of older date, collecting the same for examination in regard to the presence of the gonococcus. Laber was successful in colonizing and recognizing gonococci in pus stains found on the shirt of a man charged with rape, and on the chemise of his victim. Examine also for evidence of syphilis, remembering that both gonorrhea and syphilis may be innocently acquired.

On a child we might find evidences of inflammation due to violence, a muco-purulent discharge. If the assault was recent, blood or clots, a lacerated hymen, dilatation of the vagina, laceration of the vagina and adjacent parts.

In the case of an unmarried virginal adult evidence of inflammation from violence, muco-purulent discharge, destroyed or lacerated hymen, dilated vagina, and, if the attack was recent, bleeding-points with perhaps clots. In case penetration is alleged and the victim has not passed her urine since the assault, the first urine should be saved for microscopic examination.

This last precaution applies, of course, with still more force to married women, or unmarried women who have had previously sexual intercourse, where the only medical evidence of importance may be that of the microscope.

Any evidence of violence on other parts of the body, notably the throat, should be observed.

If an examination is made of the man charged with the offence, note any marks of violence, particularly scratch marks.

*(To be continued.)*

## SOME CASES OF SCARLET FEVER, WITH ESPECIAL REFERENCE TO CONTAGION AND PROPHYLAXIS.[1]

BY WILLIAM C. HOLYOKE, M.D., BOSTON.

SCARLET fever, in recent years, seems to be of a milder type than it was when I began practice, more than twenty years ago. Its death-rate in this State is very much less now than it was then. Such variations in type have long been observed, and it is not impossible that severe forms of the disease may again visit us, although it is to be hoped that the continued good work of the health authorities will prevent any very destructive epidemic in the future. Still, this malady, in some form, is always with us; and in large cities it would seem almost impossible to eradicate it, fostered as it is by crowding, filth, ignorance and selfishness.

Besides the oversight of the health officers, the most hopeful means of limiting such diseases should be the influence exerted by the attending physicians. It is not sufficient that the individual patient be successfully treated, but the health of the community should always be considered, and the parents or others in charge of such cases should be taught how these diseases usually spread, and the best attainable means of prevention.

So far as we know, the virus of scarlet fever is, in most instances, taken into the system with the inspired air; but a number of cases have been reported from drinking infected milk, and we may assume that it is possible for it to gain entrance through any absorbing surface with which it can come in contact.

We are more practically concerned, however, with the origin and mode of dissimination of the virus, in order that we may deal with it at its source. It may be assumed that it is given off from all the surfaces of the body of the scarlet fever patient. The most productive source is the disquamating cuticle; and when this is thrown off in the dry state, and the fine particles are floating in the air, it is in a condition most favorable for reception into the system. In the moist state, as given off from the internal surfaces, it may not be such an immediate cause of danger; but we must believe that forcible expiration can dislodge contagious particles from the air-passages, which, either in the form of spray, or dried and pulverized sputum, may be virulent even at an early stage of the sickness. It is possible that the urine and feces, if not disinfected, may contaminate the sewage and become a remote cause of trouble.

The most important means of preventing the spread of scarlet fever is isolation of the patient and the avoidance of all means by which the germs may be conveyed away until after they are disinfected. It is believed that the virus is not carried far by the air alone, although apparent exceptions to this rule have been noted. It is usually conveyed by persons or materials that have been in the vicinity of, or in actual contact with the patient.

It is probable that scarlet fever, in most cases, is not very contagious during the first day or two; and if patients are separated as soon as the rash appears, those previously exposed will commonly escape. After this, however, it is certainly contagious as long as desquamation is going on; and although this may, in some cases, cease in three or four weeks, it usually continues longer, and sometimes more than ten weeks. As a routine practice I advise isolation for six weeks from the beginning of the sickness, but sometimes find this period too short.

Our greatest difficulty is to secure proper isolation, especially amongst the poorer classes. During the height of the illness children are easily restrained, but when convalescence begins, and they beg for liberty, it is difficult to impress upon parents the duty of restraint in the interest of public health. Another source of danger is the use, during convalescence, of books and toys which are not afterwards destroyed, and which cannot be completely disinfected. There is evidently much carelessness in this particular.

I will now report a group of cases which may serve to illustrate some of the points just noticed. In the early part of the present year a number of cases of scarlet fever occurred in the home of the Boston Children's Friend Society, on Rutland Street. The home contained at that time about seventy children, of whom, as nearly as could be determined, fifty-five had never previously had the disease. The first case appeared on January 17, 1894; others followed, at first in rapid succession, then at intervals for more than three weeks, when, on February 10th there were twenty-two sick. After this there was a period of quiet for about six weeks when two others appeared, on March 27th and 31st; and finally another one on May 1st, making a total of twenty-five cases.

For a little while we were in doubt as to the origin of the trouble, but in a few days reached the only conclusion which seemed to give a reasonable explanation.

At Christmas some persons connected with one of the Sunday-schools in Newton Centre collected from their scholars a quantity of second-hand toys and picture books, which were presented to our home. According to the reports in the daily papers, scarlet fever was then prevalent in that town, so that it became necessary to close some of the schools. From recent inquiry it is learned that the increase of scarlet fever in the town of Newton, including Newton Centre, began in November, when more cases were reported than during any other of the five months of its prevalence. The toys and books, which filled a barrel, reached the home on Rutland Street, on January 2d, and were distributed to the children about eight or ten days later; and within another week the sickness began.

I have not attempted to trace the previous ownership of the toys. There would be manifest difficulty in doing so. But the facts that they were contributed by many persons in an infected district, and that a few days after their reception by the children the malady appeared, make a strong probability that some of them were infected with the germs of scarlet fever. As soon as the toys and books were suspected they were collected and destroyed.

As cases of the disease continued to appear long after the destruction of the toys, we naturally inquire whether the later cases resulted from the original cause, or from contact with the sick. In support of the first of these views we must remember that the toys and books had been in possession of the children about ten days. They had been widely scattered, and probably sufficiently handled to disengage many of the germs. It was impossible to fumigate the whole house, and it was not attempted except by burning sulphur in the playroom, where the toys were first distributed. Therefore, it was necessary to wait for the slow process of ventilation to remove the virus, which the cold weather rendered more difficult.

[1] Read before the Boston Society for Medical Observation, October 8, 1894.

As soon as the children were taken sick they were at once separated, and their bedding and clothing removed and disinfected. The rooms occupied by the sick and their attendants were in a remote part of the building, well situated to insure isolation; and, as far as possible, all communication was cut off from the rest of the house. The management was so careful and the separation so complete that I consider it impossible that any should have become infected from this source.

We may now inquire whether it is probable that the disease continued to spread from contact with those recently affected, before they were removed. In order to throw what light I can on this matter it will be necessary to examine the cases more in detail.

The children were divided into two classes, the so-called school-children, over five years of age; and the nursery children, ten in number, all under five years; I may say that the school was within the building.

The disease began with two children on January 17th, three on the 19th and three on the 20th. These eight cases occurred in the older or school children, and all were undoubtedly produced by the original cause. Then, at intervals, in the course of the next three weeks, eight more of the older children were taken sick. How these were infected may be a doubtful question. Some of them might have resulted from contact with incipient cases of the sickness, but I am inclined to believe that the original cause was still acting.

All the remaining cases happened in the nursery. The nursery children had received none of the suspected toys; and after the disease entered the home, they were kept closely in their room, and not allowed communication with the other children. But there was one exception to this. On January 24th one of these small children was allowed to leave the nursery for a few hours and mingle with the older ones in the school-room. Four days later he was taken sick. Eight days afterwards another one came down; and I may mention that this child was troubled with a cough. From three to five days after this four others became ill, and then there was a long period of rest.

Of the cases just mentioned, we need not discuss the first, in which there had been communication with the school-children. The second, occurring eight days later, is of doubtful origin; but there can be little question that the next four, following the second at intervals of three to five days, were infected by it. This seems more reasonable from considering the fact that the second child had a cough sufficient to dislodge contagious particles from the throat.

Three more cases remain to be noticed. Two of these appeared late in March, and had been joined about a week before by several convalescent children, one of whom was found to be desquamating, although seven weeks had elapsed since she was taken sick. The remaining case appeared on May 1st, and the only explanation I can give is the following: One of those who had been affected was a girl twelve years old, whose sickness was severe and followed by prolonged desquamation. This was evident for ten weeks, but at the end of seventy-four days she was given an antiseptic bath and set at liberty. Her hair was long and thick. On the day she left the sick-room she went into the nursery, where only two children remained who had not had the disease. She also combed her hair with the comb used by those children. The visit was repeated a day or two later, and six days after her first visit one of the nursery children became sick.

Of the group of cases here reported the greater number may be regarded as due to circumstances largely beyond our control, but the last three could have been prevented by exercising more caution, although it may be said that the children who carried the infection were examined before leaving the sick-room by a prudent and experienced person. These cases, however, emphasize the need of careful supervision of convalescents, and tend to confirm the belief that many instances of scarlet fever result from neglect of this precaution, or inability to carry it out.

In the way of prophylactic treatment many internal remedies have been recommended, both to the well, to prevent the development of the disease, and to the sick, to prevent its spread. The most of these are such as have an antiseptic effect; and although we may be doubtful of their prophylactic influence on the general system, there can be little question that some of them have a very favorable effect on the mouth and fauces of the scarlet fever patient, and probably render the secretions of those parts less virulent. Of those that may be classed as mildly antiseptic I still use, in most cases, the old mixture containing chlorate of potash and tincture of chloride of iron, in small and frequent doses.

Since the most fruitful source of the germs is the desquamating cuticle, it is evident that the proper management of the skin is the most important part of the prophylactic treatment.

About twenty-five years ago Dr. Budd, of Bristol, England, reported excellent results from the application of olive oil, as an aid to isolation. He usually combined a little camphor with the oil, and the application was made freely and often, and continued until the patient was "well enough to take a warm bath." Then he was well scrubbed with antiseptic soap and water every other day until four baths had been taken, when the disinfection of the skin was regarded as complete.

Since that time most of the writers whose works I have examined mention the use of oil or ointments, either plain or containing antiseptics, but not all of them insist upon this measure as a matter of much importance; and as far as my observation extends, I do not think this method of treatment is used as commonly as its merits deserve.

Since the beginning of my practice I have always used olive oil as a remedial agent during the height of the sickness; but for some years past I have ordered it very freely throughout the whole period of illness and until disquamation has ceased, for the purpose of preventing the escape of the scales bearing the germs. There may be some advantage from combining antiseptics with it, or from using thicker ointment on the hands and feet when the patient is up; but I have been so well satisfied with the use of the plain olive oil that I still continue it, and its simplicty and ease of application are qualities that also recommend it. Much depends on its thorough and long-continued use; and as many of our patients are seen only a few times, it is necessary before ceasing attendance to give explicit directions for the future management of the case. The treatment can be best carried out if the patient remain in bed for a prolonged period; but whether in bed or up, much care must be used when

the clothing is removed. Nothing should be scattered about the floor, but all materials carefully gathered in a sheet and placed at once in the receptacle for disinfection. After getting up the hands should be well cleansed and constantly anointed, and I have known some mothers to keep the patient's hands wrapped in cotton cloths to prevent the scales from escaping.

Since adopting the measures here mentioned, my impression is that the disease is much less contagious than before. I have kept no records of cases; but those of recent date can be recalled, and I remember none in private practice, within the last year when it spread to any other person after my first visit, even when isolation was impossible. Such results may be, in part, accidental, but I will mention some of the cases to show the extent of exposure.

CASE I. Family containing five children between the ages of one and eleven years, none of whom were protected by previous attack. Two of these were taken sick at the same time, and at my first visit the rash was just appearing. In one the sickness was moderately severe, in the other very mild. It was impossible to keep the other children out of the sick-room; and the mother took care of them all. Three other susceptible children in the same house were occasional visitors, but none become affected.

CASE II. Family containing five children, who had never had the disease. Ages two to twelve years. One of these, age six years, had a moderately severe attack. Rash quite abundant. Patches on tonsils. He was kept in a separate room, but the other children were on the same floor, and the mother took care of all. No other case occurred in the family.

CASE III. Family of three children, who had never previously had the sickness. Ages six to ten years. The youngest had a severe attack with abundant rash. One of the others slept much of the time in the sick-room; and they were all taken care of by the same person. The two older ones remained well.

CASE IV. Family containing four young persons, who had never had the disease. The youngest, age eight years, became affected. Rash well-marked. Isolation was impossible. The others were frequently in the sick-room; and a woman living in the same house, mother of two small children, often visited the sick boy. No other case of the sickness occurred.

Other recent cases with a like result could be reported; but I have selected those in which there was the greatest exposure of susceptible persons.

It may be said that scarlet fever, at the present time, is of a mild type and not very contagious; but the group of cases first mentioned tends to show that under certain conditions the disease may be taken now as readily as ever.

## REMARKS ON STAPEDECTOMY.[1]

BY FREDERICK L. JACK, M.D., BOSTON, MASS.

THE interest in operations for the relief of deafness, vertigo and tinnitus has naturally centered during the last two years, upon mobilization or removal of the stapes. Until within a comparatively recent time the drum was attacked, then the various tendons, and finally the two larger ossicles themselves were removed for the purpose of relieving the distressing symptoms often attending diseases of the middle ear. As time has gone on the pathology of the different portions of the ear has become better known, and it has become evident that the solution to the problem in many instances is at the further end of the chain, and efforts have been made in that direction. From our present knowledge it seems plausible to attribute the improvement in any individual case of removal of the membrana tympani, malleus or incus, in part or whole, chiefly to liberating or mobilizing the stapes.

In the last two years I have tried to remove this bone in sixty cases. As every rule has its exception, it seems that in my first series of sixteen cases reported in 1892, I hit upon many exceptions, and for the last year have been laboring with the rule.

It is very important before advising any operative interference to recognize as far as possible the changes in the sound-perceiving as well as in the sound-transmitting apparatus, for, as we know, changes in one part are apt to follow those in the other.

We know that with a perfectly open foramen ovalis and a normal sound-perceiving apparatus one is able to hear ordinary conversation with little or no difficulty. Much has been done to demonstrate the practicability of removing the stapes to free this foramen. The conditions which so frequently destroy the expected results are degeneration of the auditory nerve, bony fixation of the foot-plate, or along any part of the crura or head of the bone; rupture of the basal membrane with hemorrhage into the labyrinth at the time of extraction is an accident to be thought of. I have found in those cases operated upon early, by which I mean before a high degree of deafness has occurred, that there is much less resistance to removal of the stapes and that there is a better condition of the internal ear. The following case of double extraction, previously reported, is evidence of this. The case is also of value because of the long time which has elapsed since the operations.

CASE I. F. D., twenty years old. Progressive deafness in both middle ears from chronic non-suppurative inflammation of several years duration. Hearing in the right ear before operation was as follows: Hearing = R., H $\frac{c}{6}$; whispering voice = $\frac{s}{25}$; moderate voice = $\frac{1}{30}$.

Operation on September 27, 1892. Tests of hearing one year and eight months afterwards as follows: Hearing = R., H $\frac{1}{10}$; whispering voice = $\frac{1}{5}$; moderate voice = $\frac{1}{3}$; tuning fork, C. = a. c., 27″, B. C., 36″.

The hearing in the left ear before operation was as follows: Hearing = L., H $\frac{2}{6}$; whispering voice = $\frac{1}{5}$; moderate voice = $\frac{1}{3}$; tuning fork, C. = a. c., 15″.

The hearing power as recently tested, two years after stapedectomy, was as follows: Hearing = L., H $\frac{1}{10}$; whispering voice = $\frac{1}{3}$; moderate voice = $\frac{1}{3}$; tuning fork, C. = a. c., 25″, B. C., 28″.

The relief afforded in this case for so long a time argues well for the future.

My results in so-called cases of sclerosis have been extremely discouraging, as appeared in last year's report. For in nearly every instance the bone has been found so firmly anchylosed, usually in the neighborhood of the foot-plate, that upon pressure a fracture of the crura has occurred, leaving the foot-plate firmly adherent. In fact, as most of us have seen in one of Professor Politzer's beautiful specimens, the vestibule itself may contain osseous growths.

In the hypertrophic form of inflammation as well as in the suppurative ears which have healed, we find as

[1] Read before the Boston Society for Medical Observation, October 8, 1894.

a rule that adhesions are fibrous and not bony. Here we have a condition better adapted for mobilization or removal of the bone. But in this class of cases again, unfortunately, we have changes in the internal ear which seem to go hand in hand sooner or later with many changes around the foot-plate. As it is impossible in any case to determine beforehand the amount of relief, it seems best from the present experience, as I suggested two years ago, to make an opening in the drum membrane in order to note pathological changes as a guide to surgical interference. By means of this exploratory opening access is furnished for a syncheotomy, tenotomy, disarticulation of the incudo-stapedial joint, or removal of the incus itself, and mobilization of the stapes by means of a probe. Many of these operations can be done more successfully under cocaine with the aid which the patient is able to give, but stapedectomy should always be done under ether. If any of these measures give relief the removal of the stapes may not be necessary. In cases of chronic aural vertigo the removal of the pressure on the stapes has been found in many instances to relieve the dizziness. Let me briefly report one case which has stood the test of time.

CASE II. M. R., twenty-four years of age. There had been a chronic progressive disease in the right middle ear for two years. For the last year had been troubled a great deal with attacks of dizziness. The drum membrane was opaque, indrawn and the malleus retracted.

The hearing for the watch was: Hearing = R., H $\frac{15}{180}$; whispering voice = $\frac{1}{25}$; tuning fork, C. = a. c., 10″, B. C., 12″. Konig's rods, 25,000.

The operation was done under ether; triangular incision. The incudo-stapedial joint could not be seen; but by means of a curved knife the articulation was separated and the tendon of the stapedius divided. With a blunt hook the long process of the incus was brought down as far away from the head of the stapes as possible. It is now over one year and a half since the operation and there has been no return of the vertigo. There was practically no change in the hearing. In order to relieve the pressure in this case, disarticulation of the incudo-stapedial joint was all that was necessary. The stapes can be removed at a later operation if necessary.

In considering the results of a personal experience for the last two years, I can say —

(1) That the best results in hearing have been obtained in cases of early removal of the bone, and that this operation is of little use in cases of otitis media insidiosa (sclerosis).

(2) That cases of chronic aural vertigo have been permanently relieved by liberation of the stapes or by extraction of the bone itself.

(3) That in cases of non-suppurative disease of the middle ear, as well as the class of cases the result of a chronic suppurative process, surgical mobilization should first be tried before an attempt is made to remove the stapes.

(4) That most operations for mobilizing the stapes or freeing the oval window must be looked upon as largely experimental, and that in many cases a fracture of the crura occurs at the time of attempted extraction, leaving the base plate.

---

The *Southern Medical Review*, Houston, Texas, has published one issue, counted the cost, and is no more.

## Clinical Department.

### A CASE OF CONCEALED UTERINE HEMORRHAGE.

BY ALBERT H. TUTTLE, M.D., CAMBRIDGE, MASS.

I WAS called in consultation by Dr. Slayter, September 20th, to see a young woman, Mrs. M., a fourpara of about thirty years of age, who had been suffering from a sero-sanguinolent discharge from the vagina, of uterine origin, for over a week, and whose pallor and loss of strength indicated something unusual had taken place. Menstruation occurred last on the 25th of May, and was followed by the usual symptoms of pregnancy.

At the time of examination, about four months from the date of last menstruation, the uterus was symmetrically enlarged and at a level with the umbilicus; with a firmness that indicated a nearly solid body, and of a boggy consistency, resembling that of a mole structure. It was freely movable, not tender to the touch, and transmitted no sounds that could be recognized, either placental or fetal. There was no history of uterine pains of a labor-like character, or any symptom of the onset of labor. Vaginal examination showed a badly-lacerated, swollen cervix, with tight cicatricial constriction of the canal, the latter obviously having much to do with the patient's condition. Ballotement was negative. From the absence of signs of life and the peculiarly solid character of the uterus, the conclusion that the fetus was dead was easily reached, and advice was given to clean out the contents of the womb.

The following day, with the assistance of Drs. Slayter and Lockhart, the patient was etherized, the cervix drawn down with forceps, the canal dilated with Wathens's instrument and the fingers, and the contents of the uterus evacuated; nearly a quart of dark tarry-looking blood, with a four months' fetus, somewhat macerated, and the placenta were removed.

The dilatation of the cervix was effected with considerable difficulty, the former tear being slightly increased by the operation, and was not carried sufficiently to admit of the delivery, *in toto*, of the aftercoming head. The head was crushed by a finger passed above it, in the uterus, and extracted by the aid of a strong pair of tenaculum forceps, inserted in the firmer structures of the skull, and gentle traction on the body of the fetus. Relaxation of the uterus followed the third stage of delivery, and was met by the intra-uterine injection of tincture of iodine. An uninterrupted recovery followed.

## Medical Progress.

### RECENT PROGRESS IN GENITO-URINARY SURGERY.

BY F. S. WATSON, M.D.

#### SURGERY OF THE URETER.

FENGER,[1] at the end of a very valuable and interesting article on this subject, presents the following conclusions:

Catheterization of the ureters from the bladder for purposes of diagnosis of diseases of the kidneys has

[1] Annals of Surgery, September, 1894.

given valuable information affecting the decision for or against operation on the kidney. The procedure is reasonably practicable in the female.

In man, catheterization is practicable only through epicystotomy. The danger of this operation is steadily decreasing. Therefore this procedure is justifiable in selected cases.

Catheterization of the ureter from the bladder as a curative measure for the evacuation of hydro- or pyonephrosis has occasionally been performed successfully (Pawlik). It is more difficult and more uncertain than nephrotomy, and the attempt to find and remedy the stenosis of the ureter from the pelvis of the kidney.

Dilatation of strictures of the female ureter by elastic bougies or catheters has been tried from the bladder by Kelly with temporary success, and from the pelvis of the kidney by Alsberg successfully. Consequently this procedure is of use in isolated cases.

Permanent catheterization of the ureter from the bladder, a fistula, or an implanted ureter is often tolerated only for a limited time, and must be employed with caution for fear of causing ureteritis.

Uretero-lithotomy, longitudinal incision over a stone for its removal, is a safe operation by the extra peritoneal method. The wound heals without stenosis. In extraperitoneal operations suturing is unnecessary. Drainage down to the wound is sufficient.

Intraperitoneal ureterotomy should be done only when access outside of the peritoneal cavity is impossible, and should be completed by careful suturing, covering with a peritoneal or omental flap and drainage.

Opening of the peritoneal cavity to locate the seat of the stone may occasionally be necessary, but when the diagnosis is once made, ureterotomy for the removal of the stone should be done through an extraperitoneal incision, and the abdomen closed.

In valve-formation or stricture of the ureter, causing pyo- or hydro-nephrosis, or a permanent renal fistula, nephrotomy should be followed by exploration of the ureter in its entire course from the kidney to the bladder.

Exploration of the ureter as to its permeability should be done from the renal wound by a long, flexible silver probe — a uterine probe — or an elastic bougie, either olive-pointed or not. If the bougie passes into the bladder, the examination is at an end. The size of bougie that will pass through a healthy ureter is from 9 to 12, French scale.

If the pelvic orifice of the ureter cannot be found from the renal wound, it should be sought for by opening the pelvis, pyelotomy, or by incising the ureter, ureterotomy.

A longitudinal incision, half an inch to an inch long, in the posterior wall of the pelvis, can be made while the kidney is lifted upon and against the twelfth rib. This procedure is easy if the pelvis is dilated, but may be impossible if the pelvis is of normal size.

Operation for valve-formation should be done through the wound in the pelvis. If the opening cannot be seen or found from the pelvis, ureterotomy should be performed immediately below the pelvis, a small incision should be made in the ureter, and a probe passed up into the pelvis. The valve should be split longitudinally, and the incised borders so treated as to prevent re-formation of the valve.

A stricture in the ureter, if not too extensive, can be treated by a plastic operation on the plan of the Heinecke-Mikulicz operation for stenosis of the pylorus, namely, longitudinal division of the stricture and transverse union of the longitudinal wound. This method of operating for ureteral stricture seems to me preferable to resection of the strictured part of the ureter (Küster's operation) for the following reason: It is a more economical operation and preferable when the elongation of the ureter is not sufficient to permit the two cut ends of the ureter, after excision of the stricture not only to come in contact, but even to permit of closure by invagination without stretching.

Resection of the upper end of the ureter, and implantation of the distal end into the pelvis may be useful in rupture or division or stricture of the upper end of the ureter, as described by Küster.

In a similar case of stricture in the upper end of the ureter, especially if the ureter were not elongated or the kidney movable, I should prefer the plastic operation proposed by me, as it is easier of technique, and as it proved successful in my case of traumatic stricture in the ureter below the pelvic orifice.

The ureter is accessible through an extraperitoneal incision, a continuation of the oblique incision for lumbar nephrotomy, from the twelfth rib down along and one inch anterior to the ilium and along Poupart's ligament to about its middle. This incision gives access to the upper three-fourths of the ureter and down to within two or three inches above the bladder.

The vesical and lower pelvic portions of the ureter may be reached, as Cabot has pointed out, by means of a sacral operation, or Kraske's method modified by osteoplastic, temporary resection of the sacrum. In woman the vesical portion of the ureter is accessible through the vagina.

The vesical orifice of the ureter may be reached from within the bladder by suprapubic cystotomy in man or by dilatation of the urethra, suprapubic, or vaginal cystotomy in woman.

Uretero-uterine fistulas can be treated satisfactorily by plastic closure of the vagina or nephrectomy. Implantation of the ureter into the bladder is, under favorable circumstances, the operation of the future for this condition.

Uretero-vaginal fistulas and congenital urethral or vaginal terminations of the ureter should be treated by vaginal plastic operation for displacement of the proximal end of the ureter into the bladder. If these attempts fail, and the kidney is not infected, extra- or transperitoneal implantation into the bladder should be done, and finally, as a last resort, nephrectomy.

Complete transverse wounds in the continuity of the ureter should be treated uretero-ureterostomy, after Van Hook's method of lateral implantation if possible.

Complete transverse wounds of the upper end of the ureter should be treated by implantation of the ureter into the pelvis of the kidney, as devised by Küster.

Complete transverse wounds of the ureter near the bladder should be treated by implantation into that viscus either by splitting the ureter or by invagination.

Loss of substance of the ureter too extensive to permit of uretero-ureterostomy, or too high up to permit of implantation into the bladder, may be treated by implantation on the skin or into the bowel.

Implantation into the bowel is objectionable on account of the infection which is almost certain to follow sooner or later.

Implantation on the skin in the lumbar region or the

abdominal wall may have to be followed by secondary nephrectomy, which, however, is much less dangerous than the primary operation.

Implantation into the rectum should not be resorted to when implantation into the bladder is possible.

### ON THE TREATMENT OF URINARY FISTULÆ BY SUTURE OR RESECTION OF THE URETHRA.

In cases of obstinate urinary fistulæ which do not yield to the usual methods of treatment, Southam[2] advises resection of a bit of the urethra and suture.

The points of importance to be observed are (1) sterilization of the urine by the external administration of boric acid or salol previous to operation, and bladder washes; (2) the separation of the walls of the urethra fully from the surrounding tissues at the seat of operation; (3) avoidance of the mucous membrane in suturing; (4) in closing the external wound pass the sutures deeply to include all the tissues down to the urethra; (5) to leave a catheter in the bladder, or to catheterize at regular intervals, and use bladder washes.

### ANOTHER CASE OF PROSTATIC HYPERTROPHY SUCCESSFULLY TREATED BY CASTRATION.[3]

The patient was seventy years old, with prostatic hypertrophy and severe chronic cystitis. The prostate was as large as a man's fist. Frequent and painful urination, fever, loss of appetite, and sleeplessness, were present. Palliative treatment had but little influence. There were about 150 c. cm. of residual urine. Castration was performed, and the wound healed by first intention. Eight days later there was a perceptible decrease in the size of the prostate. At the end of fifteen days it had diminished one-third in size. In a little over two months it was of normal size. A few days after the operation urination became less frequent and painful. The bladder was washed out with antiseptic fluids, and at the end of three weeks the urine became normal. There was very marked atony of the bladder, which remained unchanged for fourteen days, after which the expulsive power of the bladder began to increase; and at the end of two months the patient, free from all bladder symptoms, could empty the bladder entirely without the use of a catheter.

### SUPRAPUBIC PROSTATECTOMY.

A. W. Mayo Robinson,[4] of Leeds, reports a series of twelve cases in which he has performed suprapubic prostatectomy during the interval including December, 1887, and January, 1894. The ages of the patients ranged from sixty-one to seventy-three years, three of them being of the latter age. Only one death was attributable to the operation. In this case the fatality was due to suppuration between the bladder and rectum caused by overdistention of the rectum by the colpeurynter. One patient died from senile asthenia some weeks after the operation, having fully recovered from it and having regained the power of voluntary urination by the urethra. The remaining ten were all restored to health, with natural powers of micturition.

The author recommends the following technique: Besides asepticizing the skin by a previous carbolic dressing, and washing out the bladder with boracic lotion, he gives the patient five to ten grains of boracic acid and a little saccharine thrice daily for a few days before operation, so as to render the urine aseptic if possible. The rectal bag, by raising the prostate nearer to the manipulating finger, is of advantage; but it is important not to overdistend it, lest rupture of the rectum or inflammation of the meso-rectum ensue, for which reason he only has four or, at most, six ounces of water introduced. The bladder is distended with boracic lotion until it can be felt above the pubes, no fixed quantity being employed. In two of his cases the peritoneum was in touch with the pubes, and in one case it was so fixed to it that he had to deliberately open the serous membrane to reach the bladder, after which he carefully separated it and closed the peritoneal opening before incising the bladder, the patient being no worse for the complication.

In removing the obstruction he has found McGill's scissors or the cutting-ring forceps invented by Jessop to answer best for the sessile or pedunclated enlargement of the middle lobe; and for the ring-like obstruction he has used the scissors, first at one side and then at the other, so as to cut out a V-shaped portion, making a clear channel from the vesical pouch straight into the urethra, down which the finger is passed to see that the passage is clear. If the lateral lobes are much enlarged, the finger can be insinuated within the capsule and the adnoid masses can be enucleated with very little difficulty. Lastly, all loose pieces of tissue are cut away, and the parts are left as smooth as possible. In order to disturb as little as possible the cellular surroundings of the bladder, the edges of the vesical opening are fixed temporarily to the margin of the wound by a suture on each side before any intravesical manipulations are commenced.

Suprapubic drainage was efficient in all cases, and it was not necessary to drain through the perineum. In the after-treatment boracic acid was given thrice daily, and the bladder was washed out once or twice daily by syringing a solution of boracic acid through from the urethra to the drainage opening. The drainage-tube was removed, if possible, on the third day, and the patient allowed to sit up within a few days of the operation. As a rule, recovery was attended with very little general disturbance or discomfort, and the urine began to be passed by the urethra soon after the patient was allowed to sit up.

He considers that the operation of suprapubic prostatectomy in properly selected cases is one attended with less danger than is usually thought, and that if thoroughly and completely performed it is capable of affording such relief as may be in many instances genuinely termed a cure, and that in a class of cases which until a few years ago were looked upon as incurable.

### CASES OF EXCISION OF CONSIDERABLE PORTIONS OF THE URINARY BLADDER.

Dr. R. F. Wier,[5] of New York, relates three cases in which he has removed considerable portions of the urinary bladder for the extirpation of neoplasms of its wall. In the first case, a man fifty-nine years of age, the cystoscope had revealed a tumor on the posterior wall. The rectum was distended by a colpeurynter and suprapubic section was done, the patient being in the Trendelenberg position. A single tumor,

[2] Lancet, July 7, 1894.
[3] Mayer and Heanel: Centralblatt für die Krank der Harn und Sexual-Organe, August 23, 1894.
[4] British Medical Journal, July 14, 1894; Annals of Surgery, November, 1894.
[5] Medical Recorder, August 11, 1894; Annals of Surgery, November, 1894.

the size of a distal phalanx of the thumb, was found on the upper part of the posterior wall, somewhat to the right of the median line. To effectually get beyond it, the peritoneum was stripped off from the summit and the posterior surface for a space reaching from one seminal vesicle to the other and down nearly to the prostate. In so doing, at one point a rent was made in the peritoneum, which was at once sewn up with silk sutures and caused no after inconvenience. A triangular portion of the posterior wall of the bladder, about two and a half inches on each of its sides, including the tumor, but going widely from its base, was finally removed. Proper suture of the lower angle of this incision was found impracticable, and so no attempt to close any portion of it was made, but the space between the bladder and the peritoneum was packed with iodoform gauze, and the bladder itself was filled with iodoform gauze packed around a rubber catheter passed to the bottom of the organ. The patient did well. His wound had very nearly closed, when he was attacked by erysipelas, which, after four days, terminated in death, seven weeks after the operation. At the autopsy it was seen that the suprapubic wound had very nearly healed, the gap in the posterior wall of the bladder had closed over by a smooth cicatricial surface.

The second case, a man, fifty-five years of age, was the subject of a carcinoma of the summit of the bladder, which also involved the overlying soft parts in the suprapubic region, presenting superficially above the pubis as a tumor of the skin about the size of an English walnut, with an indurated area surrounding its base about two inches in diameter. The cystoscope revealed a tumor projecting into the bladder on its postero-superior wall. Enlarged superficial inguinal glands existed on both sides. The external growth was circumscribed by incision, and separated from the surrounding soft tissues down to its attachment to the bladder. The peritoneum was then peeled off by a blunt dissector from the posterior wall of the bladder down to the prostate, and on each side as far as the seminal vesicles. This whole exposed portion of the bladder was then excised, including a papillomatous growth in its centre, as well as the growth rising out from the summit of the bladder, the section through the bladder walls passing at least from one-half to three-quarters of an inch beyond the growth in all directions. The bladder was sewn up without difficulty from the bottom with interrupted catgut sutures, passed through all its coats; in one or two places on its summit these were reinforced by silkworm-gut sutures, only through the muscular coat. A small opening was left towards the pubis, through which a double rubber drain-tube was inserted. The wound in the abdominal wall was packed with iodoform gauze. The patient did well after the operation, leaving the hospital eight weeks later, all healed, holding his water from three to four hours. The capacity of the bladder was from four to five ounces. Two weeks after the operation on the bladder, the glands in each groin were also extirpated.

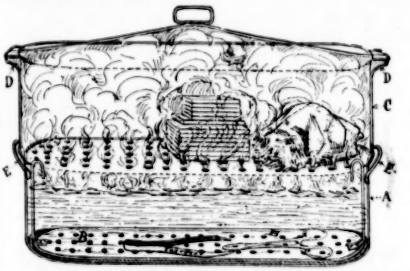
BOVINE TUBERCULOSIS IN NEW YORK STATE. — The New York State Board of Health devotes an entire volume of its fourteenth Annual Report to a review of the work done by the State with reference to bovine tuberculosis.

## New Instruments.



### FISH-BOILER PORTABLE STERILIZER.

BY W. L. BURRAGE, M.D., BOSTON.

A STERILIZER of moderate price, that is not too large or too heavy to be easily carried about, that is capable of boiling instruments in soda solution, and at the same time steaming enough towels and dressings for any ordinary surgical operation is shown in the accompanying cut.

Many of the sterilizers on the market are complicated, bulky and expensive. Most of them will steam instruments; but few, if any, have conveniences for boiling them in soda solution. Perhaps it is unnecessary to state that the advantages of boiling instruments in soda, the method in use in the Syms Operating Theatre, Roosevelt Hospital, and in many of the leading hospitals, are, first, that the instruments are not rusted, and the edges of the knives and scissors are not spoiled; and, second, that while the sterilization is perfect, the process occupies from five to ten minutes only.

The house dishpan used by some operators, is not clean, and does not well hold long instruments; and, besides, the soda discolors the tin, to say nothing of the annoyance of pouring out the water and handling the instruments when hot.

There is nothing especially original about the sterilizer I describe. I was on the point of having one made a year or so ago, when on mentioning it to a friend, he said that he himself was having one made on the same plan. His has given perfect satisfaction, and so has mine. I offer it to the profession, hoping that it may prove of value to others. When ready for use, the sterilizer consists of the granite-ware kettle (A), eighteen inches long, seven inches wide, and five and a quarter inches high, in which is the tray (B), with a handle at either end. The granite-ware cannot be corroded by the soda solution, and is, therefore, superior to tin. The kettle will hold any reasonable number of instruments. The remaining portion of the sterilizer is the steamer (C), which is nineteen inches long, eight inches wide, and seven inches high, and fits the top of the boiler. It is like any covered vegetable-steamer used in the kitchen, except that it has a small projection at either end (D) to hold the handles (E) of the boiler (A) when it is packed inside of steamer (C) for transportation.

The boiler may be bought of any kitchen-furnishing dealer, and any tinsmith can make the steamer. The weight of the sterilizer is about eight pounds, depend-

ing on the quality of the tin. It may be carried in a common canvas extension-case, such as may be bought at any trunk store. In length it just fits into the twenty-two inch size. In width, it is several inches narrower. The space between the case and the apparatus may be utilized for gauze, extra instruments, etc.

To operate, first remove the tray and fill the kettle half-full of water and put it on the stove. Place the towels, sponges, ligatures, and dressings in the steamer and put it on the boiler. After the water has boiled half or three-quarters of an hour, and ten minutes before the contents of the sterilizer will be needed, remove the steamer and put a small half-cupful of washing-soda crystals in the water of the kettle, and lower into it the tray on which the instruments have been previously placed.

Just before the patient is brought in the steamer is carried to the operating-table and the cover taken off by an assistant. At the same time the instruments are removed by the operator, who lifts up the now sterile handles of the tray and sets it on a sterilized towel, or in a pan of boiled water. Thus the instruments are ready for use without unnecessary handling.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL OBSERVATION.

J. G. MUMFORD, M.D., SECRETARY.

MEETING of October 8, 1894.

DR. WILLIAM C. HOLYOKE read a paper entitled,

SOME CASES OF SCARLET FEVER, WITH ESPECIAL REFERENCE TO CONTAGION AND PROPHYLAXIS.[1]

DR. FREDERICK L. JACK read

REMARKS ON STAPEDECTOMY.[2]

DR. G. A. LELAND said: The paper which has just been read bears a more than passing interest, since it has to do with an operation which is comparatively new in the annals of otological surgery, and may be regarded as a venture into a new field. Whether the operation will make for itself a permanent place in surgical procedures I suppose is a question that is not yet satisfactorily settled. We hear reports of cases in which it has been of great benefit; we also hear of cases where it has been of no benefit, or even where it has made the patient more or less worse, and, therefore, it must stand or fall according to whether it is able to produce more good or evil. It is, however, an attempt to do something for a considerable class of patients who have heretofore been condemned to a life of deafness unless perchance some accident should happen to relieve them, as has been the case in rare instances. Here in Boston we have occasion to be proud of this operation also, because it has been brought before the profession of the whole world in a definite, forcible way by one of our own number, namely, the reader of the paper, Dr. Jack. Others have perhaps thought of it before, and perhaps some others have attempted it, while still others have doubtless stumbled upon it in an accidental sort of way; but since these have not considered it of sufficient importance at the time to pursue the investigation further or to advocate it before the profession, that it might be tried, we must all agree that to Dr. Jack belongs all the credit of the initiation and promulgation of the operation.

As we have seen, it is an operation which is done among, perhaps, the most delicate structures of the human body outside of the brain cavity; and since the parts are so small it might rank in delicacy even with the operations upon the brain itself. It is also being performed in regions accessible with difficulty where the nature of the lesion it is often impossible to predict, and where the diagnosis always requires the careful consideration of the finest of fine points. Hence it is to be hoped that the operation, if it does nothing more startling will, at least, as Dr. Jack has said on a previous occasion, lead to finer and more accurate diagnoses where the study of pathological conditions because of the lamentable dearth of anatomical material must necessitate long and tedious observation.

At the risk of being presumptious, I might venture to utter a caution here, lest too much weight be given to favorable cases already operated upon, which, as the reader has said, have not extended back more than two years. Diseases of the ear are so insidious, cicatricial processes are so slow in their proliferation and in their ultimate hardening down, that it may not be improbable that the hearing may again be shut out, especially in cases where a previous suppurative process has obtained.

It is also probably true that only those cases should be operated upon which have been proved irremediable by every other means. This procedure should be the last resort, since it is evident that where the ossicular chain has been broken and the essential bone removed, no hope can be entertained from any further treatment by any means at present known. And this leads me still further to opine, that those ears should not be operated upon in which there is left a serviceable amount of hearing, since we are not yet sure enough of results to predict success; and even the small but exceedingly precious amount of residual hearing which may be only sufficient to keep a patient from a life of silence, should not be risked unless we are sure to be able to confer a benefit. Witness Dr. Blake's report of twenty-two cases in which a notable decrease of hearing followed extraction of the stapes. And this brings us back to what was said in the beginning, that if the operation after it has been perfected shall show that it injures more than it benefits, it will fall into disuse and merit only a place, albeit a useful one, in history.

## Recent Literature.

*Operative Surgery.* By Th. Kocher, M.D., Professor at the University and Director of the Surgical Clinic at the Berne University. 8vo, 288 pages, 163 illustrations, extra muslin. Wm. Wood & Co. 1894.

This is intended to be a book with which an operator may rapidly review operative technique. The descriptions are of operations which its author has thoroughly tested and found most efficient. His well-known skill and reputation as a surgeon are recommendations which should satisfy all. The book is what it claims to be, and is well written. The arrangement of the subject is excellent; the illustrations

well chosen; the description of operative detail clear, concise and correct. The article on "the selection of the direction of the incision" is a new feature in this class of text-book, and contains some valuable information. The list of operations described is unusual. The writer depends largely upon his plates as aids to his descriptions of anatomical detail. His style is one so intensely practical that only the important facts are presented. This makes the book best suited to the requirements of those having advanced knowledge and considerable experience in surgical work. It discusses much atypical work and could be used to advantage by a student chiefly as a supplement to the customary text-books which describe typical and routine methods. As such it is very valuable.

The work of the publisher is especially satisfactory as to paper, type, illustrations and convenient form.

*The Principles of Bacteriology.* A practical manual for students and physicians by A. C. ABBOTT, M.D., First Assistant, Laboratory of Hygiene, University of Pennsylvania. Philadelphia: Lea Brothers & Co. 1894.

While this book is more especially designed for the use of those who desire to obtain a first-hand knowledge of bacteria by practical work in the laboratory, yet the needs of others who wish only a theoretical acquaintance with the principles of bacteriology have also been borne in mind by the author. All the important methods of bacteriological investigations are clearly described, the difficulties of the beginner being carefully anticipated.

An especially valuable feature of the work is that it presents most of the time-saving and simplifying improvements on the original German technique which American bacteriologists have contributed to the science. We regret to note, however, that the rapid and thoroughly satisfactory method of preparing blood-serum culture tubes, which has been in use in Boston and elsewhere for some time, has not been given a place. The great and growing importance of cultures in the diagnosis of diphtheria in now everywhere appreciated, and the large quantities of this rapidly prepared culture media now used proves its utility, so that a full description of the method of its preparation is eminently desirable in a work of this kind.

The book is now in its second edition, and bids fair to hold its deserved success. It has been considerably enlarged and greatly improved by the insertion of additional chapters and original drawings.

*A Primer of Psychology and Mental Diseases.* By C. H. BURR, M.D., Medical Superintendent of the Eastern Michigan Asylum, etc. Pp. 104. Detroit, Mich.: George S. Davis. 1894.

This little manual is designed for the instruction of asylum nurses, and is well adapted for that purpose. If chapters on psychology and the different forms of insanity are indispensable for thorough instruction in nursing in cases of mental disease, they could hardly be clearer or more condensed than those which comprise three-quarters of this book.

The practical part, however, is the chapter on the management of cases of insanity. It finds place in the remaining quarter of the volume and to our mind might well have been amplified at the expense of the preceding chapters, with advantage to nurses and attendants; as it is full of useful suggestions and sound advice.

## BRIGHT'S DISEASE OF A PRIMARILY INFECTIOUS NATURE.

AMONG the acquisitions to medical knowledge of the last fifteen years is the demonstration of the unity of Bright's disease. Although the terms "interstitial nephritis," "parenchymatous nephritis," are still necessary in the interest of precision, they do not represent two fundamentally different pathological processes, but only modalities of one, affecting both the connective-tissue stroma and the secretory substance — sometimes one, sometimes the other, predominantly — but always with marked tendency to produce the fibroid, contracted kidney as the ultimate phase.

Gaucher has described a nephritis caused by incomplete oxidation of azotized extractives, and Da Costa has demonstrated an albuminuria in which uric acid (or uric with oxalic) seems to be the causal agent.

The old and prevalent notion, so forcibly stated by Christison and Rayer, that alcoholism is the most common cause of chronic nephritis with albuminuria (three-fourths or four-fifths of all cases, according to Christison) has not been confirmed by more recent investigations; and, if we may trust the Report of the British Investigating Committee upon Alcoholism, we must believe that "there is little connection between chronic Bright's disease and alcoholism." Other observers do not agree with so sweeping a statement; but no one disputes the agency of lead-poisoning in producing fibroid and atrophic changes of a grave and irremediable nature. The action of cold, and especially of damp cold, in engendering nephritis is contested by no one; at the same time, it is now agreed that fewer cases of both acute and chronic Bright's disease are due to this cause than were once supposed. Lecorché and Talamon even affirm that chronic nephritis due to cold alone is a rarity.[1]

The *modus operandi* of nephritic disease caused by autointoxication — by poisons introduced into the economy with food, or formed in the alimentary canal by morbid fermentations, or even fabricated by the cells

[1] Traité de l'albuminurie, etc., p. 443.

of the organism (leucomaïnes) — has been well elucidated by Bouchard and others. The kidney is the principal channel of elimination, and is itself often morbidly impressed by these agents and becomes inflamed.

The predominant rôle of infectious agents in the etiology of Bright's disease (especially of the acute form) has been within a few years brought to light. All are agreed as to the secondary infections of the kidney. The kidney becomes inflamed by the passage through it of the microbes of scarlatina, pneumonia, typhoid fever, or some other infectious disease from which the organism is suffering, or by the toxic products of microbic activity. This has been well shown by Maragliano[2] in relation to nephritis in cases of acute pneumonia; by Weinbaum[3] concerning the lesions of puerperal nephritis; by Openheim in reference to acute nephritis after varicella;[4] by Ashby and Hilton-Thompson and others, in connection with acute nephritis following diphtheria;[5] by Kompe[6] in reference to nephritis accompanying typhoid fever; and by numerous other observers in relation to the above and other infectious diseases (especially scarlatina) with sequent or complicating nephritic inflammations. The microbes of many of these infectious maladies have been detected in properly stained sections of the kidney. Thus, the pneumonia-diplococcus has been found in sections of the inflamed kidney by Neuwerk, Bozzolo, Weichselbaum, and Netter; Netter has found it in the urine. Faulhaber[7] has found the typhoid bacillus in stained sections in four cases of nephritis following typhoid fever, and the streptococcus of erysipelas has been observed by numerous bacteriologists in sections of inflamed kidney complicating that disease.

In this connection, it is interesting to note the painstaking researches of Mannaberg upon the relation of acute nephritis and the streptococci found in experimentally induced bacterial endocarditis. In eleven cases of acute Bright's disease in man the urine was found to contain streptococci; he cultivated the streptococcus, and inoculated dogs and puppies, producing an intense renal inflammation, and in the puppies an ulcerative endocarditis as well.[8] The cocci do not appear to select the kidneys as a special culture field, but in passing out through this emunctory, they inflame the glomeruli and tubes. Mannaberg looks upon these micro-organisms as the special pathogenic cause of the cases of acute Bright's disease which he reports, and states that cases belonging to this category appear to generally run a brief but quite severe course, very often terminating favorably. He remarks that the older views as to the origin of Bright's disease from exposure to cold and dampness are constantly being more and more restricted, and there are constantly being added factors of causation which have previously scarcely been conjectured.

[2] Riforma Medica, Naples, October 3, 1889.

[4] Berlin Klin. Woch., December 26, 1887.
[5] British Medical Journal, April 20, 1893.
[6] Münch. Med. Woch., March 24, 1890.
[7] Traité de Méd., t. v., p. 668.
[8] Quoted from Sajous' Annual, 1892, vol. i, L. 2.

All this is a natural outcome of the increase of our knowledge of the relation of animal tissues and functions to micro-organisms.

That there is a primary acute bacillary nephritis is also in accordance with the researches of Letzerich,[9] who has observed a number of cases of renal inflammation due to a characteristic bacillus from cultures of which he has been able to reproduce the nephritis in rabbits. But to Bamberger belongs the credit of first calling attention to this primarily infectious form, which has since been studied by Aufrecht, Litten, Babes and Perret, lastly by Fiessinger. The individuals are struck down in apparent health, and present from the onset symptoms of gastro-intestinal disorder, with fever, which is sometimes intense. The liver and spleen are enlarged; the principal nervous symptoms are headache, restlessness, delirium, modification of the pupils, prostration.[10] In two patients Litten observed stiffness and contracture of the nucha. The skin may become the seat of various exanthems, and there are often ecchymoses and hemorrhages. The urine is scanty and loaded with albumin. The infiltration of the integument is constant; the anasarca is generally, though far from invariably, limited to the lower extremities. The cases recorded by Babes and Perret, like those of Litten and Fiessinger, were not very grave ones; those which proved fatal terminating in four to six days of "convulsive or comatose uremia."

Fiessinger[11] has made many interesting observations on this form of Bright's disease. His first case gave the signal of invasion to an epidemic of acute Bright's disease in a canton of Oyonnax, in which fourteen persons in a village of five hundred came down with this disease. Only one died; the others got well in a period of time varying between six days and three weeks after having presented the ordinary symptoms of the malady in question. Eighteen months afterwards he witnessed another epidemic of acute Bright's disease in another locality, where, after a few benign cases, the disease broke out in a very virulent form. He believes in the contagiousness of the malady. In one family, a young girl was taken sick with the disease, and in less than a week her brother who had been much with her came down with symptoms of a severe character; angina, puffiness of the face, albuminuria, suppurative parotitis were incidents of the infection. Three weeks afterwards a young girl occupying the adjoining room became affected in a similar manner.

Fiessinger further relates a number of similar incidents which, he thinks, point to contagious transmission. The mother of a family was taken sick with acute Bright's disease. A daughter who had been away, came home during the mother's sickness, and fifteen days after became nephritic, with anasarca, vomiting and albuminuria. A middle-aged man occupying the same house, was taken down with Bright's

[9] Loc. cit.
[10] Semaine Médicale, May 12, 1894.
[11] Loc. cit., 1894, p. 221.

disease of hemorrhagic type, with anuria, extreme oppression, cephalalgia. Six months later his little girl contracted the same disease. These facts seem to point to something more than mere coincidence. Fernet relates similar cases;[12] Lecorché and Talamon record ten observations where the disease attacked simultaneously or successively several members of the same family, living together.[13]

Fernet thinks that primary infectious nephritis is seldom chronic. The nature of the germ is still unknown. Cultures of the blood have always remained sterile. Fiessinger made careful cultures of the urine in a typical case. He obtained colonies of the staphylococcus albus.

Mircoli has observed fourteen cases of primitive microbic nephritis in children, aged from three to ten years. All died. The autopsy disclosed in the vessels of the cortical substance and in the pyramids, masses of elongated corpuscles surrounded by a whitish capsule, arranged two by two or in series of six. It will be remembered that Mannaberg found only the streptococcus. Babes, in the urine of a patient believed to be affected with this disease, found numerous stubbed rods with rounded ends; the vessels of the kidneys contained similar rods; and there was cloudy swelling of the epithelium. These data are very uncertain. Every experimenter describes a different microbe.

Fiessinger, impressed by this fact, affirms that the clinical teachings are clearer than the bacteriological. "In one case we witness a suppurative parotitis after contagion in a nephritic patient; we note elsewhere cases of acute Bright's disease with hematuria, in the same ward with patients suffering from streptococcus-erysipelas and panaris. These facts, added to the observations of Mannaberg who cultivated the streptococcus found in the urine of eleven nephritic patients (vide supra), warrant the belief that at least in certain epidemics of acute Bright's disease the streptococcus is the pathogenic agent. I do not pretend that this hypothesis covers all the facts, and I deem it probable that there are various micro-organisms competent to produce this affection, just as ulcerative endocarditis, infectious angina, etc., may have a multiple microbic origin."

He reports, in all, thirty-four cases, with the following results: Recovery in less than a month, 28; recovery in two months, 2; acute, terminating in chronic disease, 2; deaths, 2. In several of these cases the infection was so attenuated — manifesting itself only by puffiness of the face and a little albumin in the urine — that a few days of the milk-diet treatment were followed by complete recovery. As diagnostic criteria, he insists on the character of epidemicity, and the, generally, short duration and mildness of the infectious nephrites. That some forms are very grave need not be repeated; these are classed under the head of hyperacute primary bacterial nephritis.

## SUCCESSFUL LAPAROTOMIES FOR PERFORATING TYPHOID AND PERFORATING GASTRIC ULCERS.

ABOUT three years ago Dr. Van Hook, of Chicago, reported [1] a successful case of laparotomy for intestinal perforation in typhoid fever, upon which there was editorial comment in the JOURNAL, November 26, 1891. Since then, in 1894, Netschagaw, of St. Petersburg, has reported a successful case of resection of bowel after perforating typhoid ulcer; and to-day we are glad to note another successful case reported [2] by Dr. Robert Abbe, of New York.

In van Hook's case the operation was performed nine hours and a half after the occurrence of the perforation; in Abbe's case the operation was performed nearly three days after the perforation. Abbe's case was apparently in all respects a much less favorable one for surgical interference, to judge from his statement of the conditions.

"The patient was in too low a state to be removed to a hospital, so the most complete arrangements possible were made to do a thorough operation at the house. A median incision below the navel exposed distended coils of deeply congested and greatly inflamed intestine, smeared with sticky lymph. The pelvis and lower abdomen were filled with a collection of foul, purulent, and fetid intestinal extravasation. This was feebly confined by matted coils of intestines, loosely glued together, that broke apart on being touched, but which, being recognized, enabled me to introduce clean laparotomy sponges under the upper abdominal wall, where a few coils were seen which showed more recent inflammation. Two pints of foul, purulent fluid and thick lymph were cleaned out, and the abdomen irrigated with warm and weak sublimate solution, 1 to 20,000, followed by plain warm-water irrigation.

"Search now revealed the cause. The lower part of the ileum showed many thick oval patches in its wall — their long axes parallel to that of the gut, and easily identified by touch as the gut was passed through the fingers, and shown also by increased subperitoneal hyperemia. One such inflamed Peyer's patch showed a gangrenous perforation a quarter of an inch in diameter, from which intestinal contents were seen to pump out. This was promptly closed by interrupted silk sutures, over which two layers of Halsted mattress stitches were placed, these being found to be the only suture that would hold in the tender and inflamed intestinal coat. A large abdominal tamponade of iodoform gauze was placed within the abdomen and pelvis, *and no attempt made to close the wound.* A hot black coffee and whiskey enema assisted greatly in preventing shock; the patient was put back to bed in three-quarters of an hour from the beginning of etherization.

"She passed a good night, and had a stronger pulse next morning. Pulse, 132; temperature, 102.5° F.; tympanites less. At the end of forty-eight hours after operation, as she was in good condition, except for tympanites, I removed the tamponade, reapplied a loose one, and gave five grains of calomel. This produced numerous loose movements and she felt much better. Temperature, 101.5° F.; pulse, 120. A little fluid feces leaked from the wound after the calomel action, showing that the perforation had slightly opened. This continued for two weeks, when it ceased, and the abdominal wound pursued the usual course, closing in rapidly

[1] Medical News, November 21, 1891, p. 591.
[2] Medical Record, January 5, 1895, p. 1.

by granulations, and has left a narrow and firm scar. After the third day her appetite improved and a rapid convalescence ensued."

Three years ago twelve laparotomies for undoubted intestinal perforation in typhoid fever had been reported, with one recovery (van Hook's case). Abbe adds five (including his own and Netschagaw's) to this list, with two recoveries. All five of these cases occurred in 1894. The statistics at present stand, seventeen cases with three recoveries. Probably some fatal cases have never been reported.

Dr. Newton, of Chicago, has reported one case, where operation was refused, but in which an abscess of the pelvis was opened in the perineum a fortnight after the occurrence of the symptoms, and the patient recovered.

In the same issue of the *Medical Record* containing Dr. Abbe's case, Dr. A. V. Atherton, of Toronto, reports three cases of perforation of the stomach from ulcer. In one of these there was spontaneous recovery, and death three years later, apparently from a second perforation; in another case an operation was done followed by recovery. In this case the operation was done about fifteen hours after the occurrence of perforation. The statistics of operation in cases of perforation of the stomach by ulcer were given in the JOURNAL, November 15, 1894, p. 495, though two unsuccessful cases — one by Weir, of New York, and one by Mouisset, of Lyons — were omitted. The importance of early operation, within the first fifteen hours, was then emphasized, and this Dr. Atherton reiterates in reviewing his cases.

Dr. Abbe justly says that perforation, in whatever part of the gastro-intestinal tract it may occur, is still perforation. He does not see why there should be one procedure for appendicitis and another for typhoid fever, and he thinks operative treatment for the treatment of typhoid perforation will be popularized and perfected, as it has been for appendiceal perforation. The chief discouragements hitherto to a greater readiness to insist upon operation have been the low condition of typhoid patients and the unfavorable condition of the intestinal wall. Experience, however, begins to teach that to modern surgery these are not insuperable obstacles; though we still fear that a degenerated heart muscle, accompanying collapse, and the condition of the gut wall will militate against a large percentage of successful cases. The strongest argument in favor of interference under such circumstances must continue to be the fatality of non-interference. Early operation after waiting for recovery from the first collapse and an open abdominal wound are generally advised.

## MEDICAL NOTES.

POSTPONEMENT OF THE DERMATOLOGICAL CONGRESS.— Dr. Geo. T. Jackson informs us that the Third International Dermatological Congress will not be held this year, as proposed. It is possible that it may not be held until 1897.

HONORS TO DR. ROUX. — Dr. Pierre Paul Emil Roux has been promoted to the ranks of Commander in the Legion of Honor, for "Exceptional services rendered to science and humanity."

INFLUENZA IN THE CHANNEL SQUADRON. — According to the *Medical Press* an outbreak of influenza has occurred in the British Channel Squadron. The two warships mainly infected are the *Royal Sovereign* and *Endymion*, upon board of which about ninety cases are at present under treatment. In consequence of the outbreak the squadron was to spend Christmas at Gibralter.

THE TRANSMISSION OF CHOLERA BY FLIES.— Dr. McCrae thinks that in the epidemic of cholera which took place last year in Gaya Jail, in India, the contagion took place through the agency of flies. Positive proofs of the transfer of the bacilli by flies in this epidemic have not yet been obtained, but the experiments of Haffkine are suggestive. Jars of sterilized milk were left exposed to the air, and consequently to the flies, which were numerous in the jail; within a short time Haffkine was able to demonstrate the presence of comma bacilli in the milk. As fully explained in an editorial in the JOURNAL for February 16, 1894, the possibility of the transmission of cholera by flies has been proved, and their agency in the spread of the New York cholera epidemic was shown to be probable.

THE RELATIONS OF ANTITOXIN TO THE COMPLICATIONS OF DIPHTHERIA.— In No. 51 of the *Deutsche Med. Wochenschrift*, Treymann describes a case of acute hemorrhagic nephritis occurring in a case of diphtheria treated by Behring's antitoxin. The attack, which occurred after an injection given on account of a slight recrudescence of the disease after the worst was over, leads Treymann to conclude, that inasmuch as ordinarily the nephritis of diphtheria occurs at the height of the disease, this attack must have been due to the antitoxin treatment. In order to disarm the unjust criticism which would with certainty be made of the treatment on account of this case, Schwalbe publishes in the same journal an account of an acute hemorrhagic nephritis occurring (also during convalescence) in a case of diphtheria not treated by antitoxin. He (Schwalbe) remarks that in the nephritis of diphtheria, in contradistinction to that of scarlet fever, blood is seldom present in the urine, a fact which would be almost certain to result in a hemorrhagic nephritis being ascribed to the new remedy. He, therefore, very justly concludes that he ought to publish his case in which the disease occurred independently of serum treatment!

A FATAL CASE OF POISONING BY QUASSIA. — Ferdinand Venn, M.D., of Chicago, in a letter to Dr. H. C. Wood published in the *University Medical Magazine* for this month, reports a case of fatal poisoning from a decoction of two ounces of quassia injected into the rectum of a child for the treatment of seat worms. The rectum was not perforated by the

nozzle of the syringe. According to Dr. Wood, this is the only case on record of poisoning by this drug, although the experiments of Hoppe have shown that the active principle is a poison in frogs, especially affecting the nerve trunks and muscles. Fifteen milligrammes of it have caused disagreeable symptoms in man, among them being evidences of toxic gastro-enteritis.

KOCHER'S METHOD FOR THE REDUCTION OF OLD DISLOCATIONS OF THE HUMERUS. — Morton, in the *Philadelphia Polyclinic*, December 15, 1894, reports three cases in which the attempt to reduce subcoracoid dislocations of the humerus of long standing by Kocher's method has resulted in fracture of the surgical neck. He therefore concludes that by this method special strain is brought upon the surgical neck of the bone, and that while it is the method of election in fresh cases, in cases of long standing other methods should be given preference.

SUCCESSFUL OPERATIONS FOR DOUBLE ANEURISM. — Quenu presented at the Academy of Medicine in Paris, on November 4, 1894, a patient thirty-six years old, upon whom he had successfully performed extirpation of an aneurism of the right external iliac artery on December 5, 1893. The aneurism occupied the whole right iliac fossa, and was as large as the head of a child at term. Sixteen days later an aneurism of the left femoral artery in the inguinal region was extirpated in the same patient. Recovery was uneventful, and at the time the patient was shown, he had been for a month following his occupation, as a clown at the Nouveau Cirque.

A REORGANIZED "SCIENCE." — The weekly journal, *Science*, is to be published the present year under the direction of an editorial committee in which each of the sciences is represented by a man of science who is at the head of his department. Among the members of the committee are Prof. H. P. Bowditch of Harvard University (physiology), and Dr. J. S. Billings of Washington (hygiene).

### BOSTON AND NEW ENGLAND.

SUPPORT FOR THE INDEX MEDICUS. — The Boston Society for Medical Improvement, at its annual meeting January 7th, appropriated a certain sum from its reserve funds for the support of the *Index Medicus*, on condition that similar steps should be taken by other societies and institutions in Boston and other cities, which are or ought to be interested in securing the continued publication of this valuable periodical.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, January 9, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 97, scarlet fever 52, measles 71, typhoid fever 6.

BEQUEST TO THE MASSACHUSETTS GENERAL HOSPITAL. — Under the will of the late Henry Saltonstall, the Massachusetts General Hospital receives, at the death of his widow, $10,000, and a further sum, in common with Harvard College and the Institute of Technology from the residue of the estate.

THE FREE HOSPITAL FOR WOMEN. — The new Free Hospital for Women on Cumberland Road, Brookline, was dedicated on January 1st, and opened for the reception of patients on the following day. The new, commodious and thoroughly equipped building forms a marked contrast to the inconvenient and contracted quarters on East Springfield Street, where the excellent work of the institution has been carried on for nineteen years.

THE NORTHAMPTON LUNATIC HOSPITAL. — The thirty-ninth annual report of the trustees of this institution shows that during the year ending September 30, 1894, 652 cases were treated. The daily average of patients in the house was 494.11. Thirty cases were discharged as recovered, 14 much improved, 28 as improved, 36 as not improved. The report states that the number of acute cases increases each year, and with this increase comes increased work in caring for them, and the necessity for more attendants. A new dormitory has been completed during the year, an excellent system of ventilation installed, and various other improvements made, including heating apparatus, elevators, apparatus for the laundry, etc. The trustees express "their satisfaction with the superintendent and his assistants for their faithful and efficient service in the care of the patients and the successful management of the institution."

CLOSE OF THE INVESTIGATION OF BOSTON PUBLIC INSTITUTIONS. — The readers of the JOURNAL have without doubt followed the accounts of the investigation of the Boston Public Institutions, which has been dragging its slow length along throughout the summer and autumn, in the daily papers. The close of the investigation will be hailed with relief. The report of the majority of the committee on the care and management of public institutions was accepted by the Board of Aldermen by a vote of eleven to one, the one dissenting vote being cast by the framer of the minority report. In the main the majority report inclined to ascribe the evils which had been brought out in the course of the investigation to the system of management, and not to those in charge of the various institutions, and advocated changes in the system, rather than in the *personnel* of the management. The minority report, on the other hand, recommends an entire change in the make-up of the Board of Commissioners of Public Institutions, as well as the removal of the entire force which is at present in charge of the institutions down the harbor. It is noteworthy that the abuses brought out by this investigation, and the changes deemed necessary, were, as was to be expected, in the main the same as were brought out in the report of the committee previously appointed by the mayor to visit the institutions and report as to their condition and management.

NEW YORK.

THE NEW YORK COUNTY MEDICAL ASSOCIATION. — At the meeting of the New York County Medical Association, held December 17th, a resolution was adopted protesting against the appointment by Governor-elect Morton of a homeopathic practitioner to supersede Dr. Joseph D. Bryant in the position of Surgeon-General of the State. At the same meeting Dr. A. G. Am Ende read a paper on the "Treatment of Diphtheria," in which he reported some remarkably good results from the local use of boroglyceride and the systematic internal administration of quinine in solution. Out of one hundred cases treated by him in the last three or four years, there were but four deaths, and in these, he claimed, the circumstances were such when the patients were first seen as to render a fatal result almost inevitable. Cases that were promptly treated, he said, seldom lasted over five days, and were generally convalescent before that. The boroglyceride was applied hourly to the fauces by means of a small camel's hair brush. The nasal passages were very rarely invaded by the diphtheritic process, but where this was the case he employed a douche of chlorate of potassium and boric acid.

THE APPROPRIATION FOR THE BOARD OF HEALTH. — The Board of Estimate and Apportionment has fixed the appropriation for the Board of Health for the year 1895 at $451,880, and in this amount is included $30,000 for the purpose of producing antitoxin. The appropriation for the Department of Charities and Correction was $2,467,521, and among the items included are $10,000 for vapor and sulphur baths in Bellevue Hospital and $35,000 for the employment of more attendants in the city asylums for the insane.

DEATH OF THE OLDEST NEGRO WOMAN IN AMERICA. — Millie Jefferson, believed to have been the oldest negro woman in America, died at the residence of her great-grandson in New York on December 17th. The date of her birth, March 30, 1785, is definitely known; so that at the time of her death she was one hundred and nine years, eight months and sixteen days old. She was born on the plantation of Thomas Jefferson in Virginia and married the body-servant of that distinguished statesman. Three of her nine children survive her and there are fifty-seven grandchildren and twenty-six great-grandchildren living. After the Civil War she moved from Virginia to Louisiana, and had resided in New York only for the last eight years.

A TEST OF NEW YORK ANTITOXIN. — During the past week the first antitoxin prepared under the auspices of the Board of Health has been put to practical use, and Drs. Biggs and Park have expressed themselves as satisfied with its qualities. It is now being employed in the treatment of diphtheria patients at both the Willard Parker and Riverside Hospitals.

A DECREASE IN THE DEATH-RATE. — During the year 1894 there were reported 41,412 deaths in the city. Of these, 17,622 were in children under five years of age, and 26,149 were among the tenement-house population. This is a considerable decrease from the preceding year, and the diminution in the death-rate is specially marked in the tenement-house districts.

OYSTERS AND TYPHOID FEVER. — At a meeting of the State Fish and Game Commission held in Albany January 4th, the State Oyster Inspector presented a report in which he stated that he had fully investigated the subject of the possibility of oysters becoming contaminated with typhoid fever germs while undergoing the "floating process," and that he had found but one stream, situated on Staten Island, where such danger existed. He was ordered by the Commissioners to demand a discontinuance of the use of this stream.

THE NEW HEALTH OFFICER OF THE PORT OF NEW YORK. — The profession is generally well pleased with the appointment by Governor Morton of Dr. Alvah H. Doty to the position of Health Officer of the Port of New York, to succeed Dr. Jenkins. For many years Dr. Doty has been in the service of the Board of Health and he has won distinction by the excellent work which he has done in all the different positions that he has held. He was born in Albany and studied medicine in the Bellevue Hospital College, New York, from which he was graduated with high honors in 1878. He soon afterwards became attached to the Health Department; and after serving in various capacities was promoted in 1892 to the head of the Bureau of Contagious Diseases. He is also surgeon of the Ninth Regiment of the National Guard.

DEATH OF DR. GOLDTHWAITE. — Dr. Henry Goldthwaite, for the past sixteen years the resident physician of the Fifth Avenue Hotel, and one of the most highly esteemed practitioners in the city, died of apoplexy on January 3d. He was born in Mobile, Alabama, April 13, 1842, and was graduated at Princeton in 1860. At the beginning of the late war he entered the Confederate service as a private, and eventually rose to the rank of Major. After the war he engaged in the banking business and for a time had charge of the Southern interest of the firm of Brown Brothers. He then decided to study medicine, and in 1876 was graduated from the Bellevue Hospital Medical College, New York. For a number of years he was in the corps of instructors at Bellevue, and up to the time of his death was one of the visiting physicians at Charity Hospital on Blackwell's Island. A widow and one son and daughter survive him.

## Miscellany.

### THE NEW YORK MEDICAL COLLEGE.

"A SHORT Sketch of the New York Medical College, with its Charter and Complete List of the Officers and Graduates," is the title of an interesting pamphlet prepared in 1883 by the late Edwin Hamilton Davis, M.D., and found among his papers. It is published for the following excellent reasons:

"The college, in 1858–9, had the misfortune to lose thirty odd diplomas, under the following circumstances: the class had been examined, the diplomas ordered and properly signed by the faculty, and awaiting the insertion of the names of the graduates, when, a few nights before the Commencement, a violent storm occurred which blew off a sky-light and deluged the closet where the parchments were kept. A new set was ordered and the damaged ones were carelessly left uncancelled.

"Some months after this occurrence, the janitor of the college was dismissed, and with him disappeared the wrinkled diplomas. It was discovered afterwards, that he had disposed of many of them in this country, and a few in London, as two have been sent from the latter place to our city authorities for certification. The late law requiring physicians to register their diplomas has brought to light quite a number here. These facts show how important it is to place in the hands of the profession a complete and authentic list of its graduates. Another reason for this publication is, that since the college closed in 1864, its alumni feel somewhat as orphans, and desire to have something to show that their *alma mater* was a veritable institution, and highly respected."

The college obtained its charter from the New York Legislature in 1850, in the interest of higher medical education. The institution struggled along for ten years without sufficient patronage, although upon its faculty were the names of many men of high standing in the profession. Fearing still greater losses owing to the withdrawal of Southern students occasioned by the war, the faculty, nine in number, resigned. On April 21st, the school was reorganized with a new faculty. During the next three years there were numerous changes in the faculty; and finally, in 1864, the college building was sold, and the school discontinued.

## "A MEDICAL MAN AS PARTNER."

THE *Australasian Medical Gazette* publishes the following:

TO THE EDITORS OF THE AUSTRALASIAN MEDICAL GAZETTE. SIRS, — Being a curious sort of character, I answered the following advertisement: "Wanted, a Medical Man as PARTNER, to tour the colonies, good paying proposition. Address, Bohemian, Herald Office," which appeared in the *Sydney Morning Herald* of October 6th, with the result that I obtained the answer which I thought would be interesting to your readers. Trusting that no man will disgrace our noble profession by accepting such an appointment, I am, etc., EAGLE EYES.

[ANSWER.]

6 FISHER'S RESERVE, PALACE STREET, PETERSHAM, October 8, 1894.

DEAR SIR, — Re proposition to tour the colonies. My proposition is to make a tour of the colonies, so that pleasure and profit will result therefrom. "Briefly," the *modus operandi* is to hire a Hall in each town we visit, and advertise a course of medical lectures on the "Social Evil," "Population Question," etc., etc. One lecture showing the fallacy of the "Malthusian Theory," and the injury of the checks advocated by Mrs. Besant, and introducing superior methods of preventing large families, etc., etc. These are burning questions with the masses and information concerning them would be eagerly sought. Another lecture, on the "Cause and Cure of Contagious Diseases," describing the latest scientific methods of curing such disease, also how to positively prevent contagion, etc. I will undertake to deliver these lectures in a clear, logical, and humorous manner, and advertise from the platform the necessity of securing skilled advice for various ailments at a nominal cost, etc. You could attend to the patients, etc., at stated hours during the day. Now, if you think favorably of my proposition, let me know and I will meet you by appointment and we can arrange the details. I am sure there is plenty of money to be made if taken in hand and worked properly. But if you are circumscribed by ancient notions of medical "ethics" and such like nonsense you will let custom dominate your reason and miss the opportunity. Further particulars when we meet.

Yours faithfully,
BOHEMIAN.

## UNUSUAL MALFORMATIONS OF THE BRAIN.

AT the meeting of the Association of American Anatomists in New York on the 29th of December, in connection with the general subject of "The Significance of Anomalies," Prof. B. G. Wilder showed three remarkable specimens from the collection of Cornell University.

(1) An adult human brain with a complete interruption of the central fissure. The total number of such cases recorded does not exceed twenty.

(2) A sheep's brain lacking the callosum or great cerebral commissure. Several human brains with this defect have been described, but the only other cases in animals are three cats, all in the Cornell Museum.

(3) A three months' human fetus where the left olfactory bulb, commonly rudimentary, is half as long as the cerebrum, as in most of the lower animals, and contains a considerable cavity. It has long been a belief of Professor Wilder that the olfactory apparatus is primary and of great morphologic importance; that the recognition of food by the smell was once more essential than reflection upon its qualities. The specimen in question, believed to be unique, suggests the possibility of reversion toward a far-off ancestral type.

## THE IMMUNITY CONFERRED BY AN ATTACK OF INFECTIOUS DISEASE.

MAISELIS,[1] has published important statistics bearing on the subject of the length of the periods of immunity conferred by attacks of infectious disease. This well-known principle, which is the basic principle of the work of Jenner, Pasteur, Koch, Behring, and of all the workers in the field of serum therapeutics, has been misstated by various writers on medicine, some of whom affirm that the survival from one attack of an infectious disease confers life-long immunity. Gregory,[2] for instance, says: "The immunity against a second attack of an infectious disease is one of the most universal and important principles in pathology. It is applicable not only to variola, measles, etc., but to all diseases which are due to a poisonous influence or miasm." Samuel[3] says: "By the survival of a single attack of an infectious disease, immunity is generally conferred for the remainder of life." The same opinion has been expressed by Hebra, Henoch, Thomas,

[1] Virchow's Archiv, vol. cxxxvii, No. 3.
[2] Vorlesungen über die Ausschlagefieber.
[3] Eulenberg's Real Encyclopedia, second edition, vol. x.

with regard to the acute exanthemata; by Griesinger, Murchinson, Zuelzer, as to typhoid fever; Audouard as to Asiatic cholera.

On account of the great theoretical and practical interest of the question, Maiselis has collected from literature the following authenticated cases of repeated attacks of infectious diseases in the same patient:

SMALL-POX.— Two attacks, 526 cases; three attacks, 9; seven attacks, 1; total, 536.
SCARLET FEVER.— Two attacks, 144 cases; three attacks, 7; four attacks, 1; eight attacks, 1; seventeen attacks, 1; total, 154.
MEASLES.— Two attacks, 103 cases; three attacks, 3; total, 106.
TYPHOID FEVER.— Two attacks, 203 cases; three attacks, 5; four attacks, 1; total, 209.
ASIATIC CHOLERA.— Two attacks, 29 cases; three attacks, 3; four attacks, 2; total, 34.

In order to avoid the danger of including cases in which relapse might have been mistaken for a second attack, only those cases have been included in the preceding tables where the interval between the attacks was sufficiently long to preclude the possibility of the second or third attacks being relapses.

Considering the fact that all cases of second attacks of infectious disease are not recognized, and that the deeply-rooted belief in immunity among the laity, as well as among physicians, often renders the diagnosis of a second attack difficult to establish, one is led to believe that repeated attacks of infectious diseases may not belong to the rarities in medicine. This consideration also tends to establish the analogy between the immunity conferred by natural and artificial processes. The quantitative principle of immunity suggested by Ehrlich and systematically elaborated by Behring applies also to the natural processes of immunization.

It seems probable that so many difficulties would surround an exact determination of the period of immunity conferred by a given attack of infectious disease, that no exact statement of the safety period could be applied to particular cases. If a child is taken with scarlet fever, we have no means of estimating the amount of toxin absorbed, or the length of time the so-called natural antitoxin of the disease is present in effective quantity. The period of immunity conferred by the injection of given quantities of the artificial antitoxin of approximately known strength, is a matter of doubt and study; and the estimated length of the period of immunity, as defined by Behring himself, has lately been changed. If the period of immunity is so difficult to compute in a case where we can approximately calculate the amount of antitoxin injected, how much more difficult will it be to calculate that conferred by the absorption of an unknown amount of toxin, and consequent antitoxin production?

## Correspondence.

### CANCER OF THE UPPER LIP, ETC. CORRECTION.

DENVER, COLO., January 2, 1895.

MR. EDITOR: — Permit me, if you please, to correct the JOURNAL'S error in the heading of my very brief note on page 640 of the issue of December 27th. It should read: "Fairly Extensive Cancer of the Upper Lip; Excision; Freedom from Recurrence at End of Three Years." And line 26 should be made: "a *fair* margin of healthy tissue" etc. Very truly yours,

CHARLES A. POWERS, M.D.

### METEOROLOGICAL RECORD,

For the week ending December 29th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Newburyport | 14,073 | 3 | 1 | — | 66.66 | — | — | — |
| Amesbury | 10,920 | 3 | 0 | — | — | — | — | — |

Deaths reported 2,186: under five years of age 631; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 318, acute lung diseases 341, consumption 273, diphtheria and croup 183, scarlet fever 38, typhoid fever 35, diarrheal diseases 29, whooping-cough 11, measles 9, erysipelas 4, malarial fever 4, small-pox 3, cerebro-spinal meningitis 2.

From diarrheal diseases New York 9, Philadelphia and Holyoke 3 each, Brooklyn, Cleveland, Pittsburgh, Fall River and New Bedford 2 each, Providence, Charleston, Lowell and Salem 1 each. From whooping-cough New York 8, Brooklyn 2, Philadelphia 1. From measles New York 5, Philadelphia, Brooklyn, Pittsburgh and Providence 1 each. From erysipelas New York 3, Boston 1. From malarial fever Brooklyn 2, New York and Charleston 1 each. From small-pox Philadelphia 2, Brooklyn 1. From cerebro-spinal meningitis New York and Boston 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,458,442, for the week ending December 22d, the death-rate was 18.2. Deaths reported 3,649; acute diseases of the respiratory organs (London) 325, measles 139, whooping-cough 70, diphtheria 60, fever 48, diarrhea 40, scarlet fever 32, small-pox (London, Birmingham and Liverpool 1 each) 3.

The death-rate ranged from 11.3 in Plymouth to 26.7 in Preston; Birmingham 18.0, Bradford 19.1, Croydon 14.0, Hull 19.4, Leeds 21.7, Leicester 14.9, Liverpool 22.6, London 17.4, Manchester 22.2, Newcastle-on-Tyne 18.3, Nottingham 15.6, Sheffield 16.5.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 29, 1894, TO JANUARY 4, 1895.

The leave of absence on surgeon's certificate of disability granted MAJOR WASHINGTON MATTHEWS, surgeon, is extended four months on surgeon's certificate of disability.

The order assigning CAPTAIN JAMES D. GLENNAN, assistant surgeon, to duty at Fort Snelling, Minnesota, is revoked.

The order assigning FIRST-LIEUT. HENRY A. SHAW, assistant surgeon, to duty at Fort Niobrara, Nebraska, upon the abandonment of Fort McKinney, Wyoming, is so amended as to direct him to report for temporary duty at Camp Merritt, Montana, and upon the completion thereof to proceed to Fort Snelling, Minnesota, for duty at that post.

Leave of absence for one month, on surgeon's certificate of disability, with permission to leave the limits of the Department is granted FIRST-LIEUT. JAMES M. KENNEDY, assistant surgeon.

Leave of absence for one month, to take effect about December 24, 1894, is granted MAJOR ROBERT H. WHITE, surgeon.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 5, 1895.

MICHAEL BRADLEY, medical director, detached from duty as a member of the Naval Examining and Medical Boards.

B. H. KIDDER, medical director, ordered as member of the Naval Examining and Medical Boards.

J. B. BARKER, surgeon, ordered to special duty in connection with the investigation of the Ford Theatre disaster.

LEWIS H. STONE, passed assistant surgeon, promoted from assistant surgeon.

F. J. B. CERDEIRO, passed assistant surgeon, ordered to study the subject and make a report to the Department of the therapeutic value of antitoxin in the treatment of diphtheria and croup.

## OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SIXTEEN DAYS ENDING DECEMBER 31, 1894.

PURVIANCE, GEORGE, surgeon. Relieved from command of service at Philadelphia, Pa., and detailed as medical inspector of immigrants at that port. December 18, 1894.

MEAD, F. W., surgeon. Directed to proceed to New York, N. Y., for temporary duty. December 27, 1894. To rejoin station (Washington, D. C.). December 29, 1894.

CARTER, H. R., surgeon. Granted leave of absence for twenty-four days, in lieu of leave granted November 20, 1894. December 21, 1894.

PECKHAM, C. T., passed assistant surgeon. To inspect unserviceable property at San Francisco Marine-Hospital. December 26, 1894.

KALLOCH, P. C., passed assistant surgeon. To report at Bureau for special temporary duty. December 29, 1894.

BRATTON, W. D., passed assistant surgeon. Placed on "Waiting Orders," to date from January 1, 1895. December 26, 1894.

MAGRUDER, G. M., passed assistant surgeon. Granted leave of absence for ten days. December 22, 1894. Leave of absence extended five days. December 31, 1894.

PERRY, T. B., passed assistant surgeon. To proceed to New York, N. Y., for temporary duty. December 28, 1894.

COBB, J. O., passed assistant surgeon. Granted leave of absence for three days. December 28, 1894.

PERRY, J. C., passed assistant surgeon. To proceed to Philadelphia, Pa., and assume temporary command of Service. December 18, 1894.

NYDEGGER, J. A., assistant surgeon. Granted leave of absence for three days. December 18, 1894.

BLUE, RUPERT, assistant surgeon. To proceed to San Francisco, Cal., for duty. December 18, 1894. Granted leave of absence for six days. December 24, 1894. To proceed to Cincinnati, O., for temporary duty. December 28, 1894.

PROCHAZKA, EMIL, assistant surgeon. Granted leave of absence for twenty-five days. December 17, 1894.

CUMMING, H. S., assistant surgeon. Leave of absence granted, November 27, 1894. Cancelled. December 20, 1894. Granted leave of absence for seven days. December 31, 1894.

## JEFFERSON MEDICAL COLLEGE.

### CLASS OF 1879.

Many members of the *Class* of 1879 *Jefferson Medical College* of Philadelphia are desirous of having a class reunion on the occasion of the fifteenth anniversary of their graduation. Owing to changes, comparatively few addresses are known and therefore this means is resorted to, with the hope that every member of the class of 1879 who reads this notice will communicate at once with the class President, Dr. Philip R. Koons, Mechanicsburg, Cumberland County, Pennsylvania.

## HARVARD MEDICAL SCHOOL.

### EVENING LECTURES.

The next lecture will be given on Thursday evening, January 17th, at 8 o'clock, by Prof. H. C. Ernst. Subject, "Tuberculosis." Physicians are cordially invited.

## SOCIETY NOTICES.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday evening, January 16th, at 8 o'clock.

Dr. G. G. Sears: "Remarks upon 200 Cases of Phthisis, Recently Seen."

Dr. F. H. Osgood: "Tuberculosis Among our Neat Cattle."

JOHN L. AMES, M.D., *Secretary*.

MASSACHUSETTS MEDICAL SOCIETY, MIDDLESEX SOUTH DISTRICT.— A meeting for medical improvement will be held at the Medical Library, 19 Boylston Place, Boston, Thursday, January 17, 1895, at 4 o'clock P. M.

Papers: "Causes of Sudden Death," Dr. T. M. Durrell. Discussion opened by Drs. F. W. Draper, W. D. Snow and J. A. Mead.

"Treatment of Diphtheria," Dr. F. G. Curtis. Discussion opened by Drs. J. L. Hildreth and E. R. Cutler.

Members of the Massachusetts Medical Society of other Districts cordially invited to be present.

ALBERT AUGUST, M.D., *Secretary*.

## RECENT DEATHS.

JONATHAN WHEELER BEMIS, M.D., M.M.S.S., died in Cambridge, January 6, 1895, aged eighty-four years.

DAVID WORTHINGTON MINOR, M.D., M.M.S.S., died in Ware, Mass., January 2, 1895, aged seventy-four years.

DR. WILLIAM GRAY DISBROW, a graduate of the class of 1857 in the Harvard Medical School, died at Dalhousie, New Brunswick, on December 12th. He was born in St. John in 1830.

MR. THOMAS LEACH, medical inspector, U. S. N. (retired), died at his home in Newmarket, N. H., December 30th, aged fifty-eight years eight months. Mr. Leach served on the *Monongahela* during the Rebellion.

## BOOKS AND PAMPHLETS RECEIVED.

The Fourteenth Annual Report of the New York State Board of Health. Two volumes and maps. Albany: Published by the State. 1894.

Transactions of the Colorado State Medical Society, Twenty-fourth Annual Convention, By-Laws and List of Members. Denver, June, 1894.

The Twenty-seventh Biennial Report of the Trustees, Superintendent and Treasurer of the Illinois Institution for the Education of the Deaf and Dumb at Jacksonville. Springfield, Ill. 1894.

Practical Uranalysis and Urinary Diagnosis; a Manual for the Use of Physicians, Surgeons and Students. By Charles W. Purdy, M.D., Queen's University, Professor of Urology and Urinary Diagnosis at the Chicago Post-Graduate Medical School, etc. With numerous illustrations, including photo engravings and colored plates. Philadelphia: The F. A. Davis Co. 1894.

# Original Articles.

## THE IMPORTANCE OF BACTERIOLOGICAL INVESTIGATIONS IN CASES OF DIPHTHERIA.[1]

BY J. H. McCOLLOM, M.D.

In September, 1893, a series of observations in cases of suspected diphtheria was commenced at the Bacteriological Laboratory of Harvard Medical School. From September, 1893, to October, 1894, 500 cases were examined, and of this number 133 proved to be diphtheria, or 26.6 per cent. These observations have been essentially different from any attempted, thus far, in this country; for they have been dealing not with the well-marked characteristic cases of diphtheria, but with the mild and doubtful cases in which a diagnosis is impossible without a bacteriological examination.

It is now generally conceded that the presence of the Klebs-Löffler bacillus is positive proof of the existence of diphtheria, and that persons in whose throats this organism is found are sources of danger to the community, and that they continue to be sources of danger so long as this organism continues to exist. Much has been said regarding the existence of the pseudo-diphtheria bacillus; and an attempt has been made by some observers to throw discredit upon the important discovery of Klebs and of Löffler. While it is perfectly possible that in certain rare instances a bacillus of a non-virulent type morphologically similar to the diphtheria bacillus may be found in persons with normal throats, still this occurrence is so exceptionally rare that it does not have any very important bearing on the accuracy of bacteriological diagnosis. It has also been claimed by some members of the profession that the inoculation of the tubes was extremely difficult, and that for this reason this method of diagnosis was not of practical use. In reply to this, it may be said that of the 800 tubes inoculated, there were only six cases in which there were no growths. This would seem a sufficient answer to the statement that this method of diagnosis is not of practical use. Any one who has had any experience in diphtheria knows perfectly well, that in a family of four or five children, one or two may have perfectly characteristic attacks of the disease, while the remaining children, without having any constitutional disturbance, without having any membrane in the throat, may have a slight seropurulent discharge from the nose which has nothing of itself characteristic of diphtheria, and in which a diagnosis of diphtheria could not possibly be made without a bacteriological examination. Many such cases have been examined during the past year, and in a large percentage of them diphtheria bacilli were found, the virulence of which was proved by their action on guinea-pigs. The occurrence of diphtheria during an attack of scarlet fever has been considerably overestimated by the profession. In these investigations 36 cases of scarlet fever in which there were marked throat symptoms were examined, and in nine of them diphtheria bacilli were found. The number of cases of measles, with marked throat symptoms, examined, is too small from which to form any satisfactory conclusions. In these investigations the average length of time in which the diphtheria bacillus was found present, has been $15\frac{1}{2}\frac{8}{9}$ days. In one instance the diphtheria bacillus was found to exist 72 days, but in this particular case it is a question whether or not there was a re-infection.

A short history of a few of the cases examined may be of interest.

In Case 15 the physician gives the following history: A boy, five years of age, complained of slight sore throat, and had a small white spot on one tonsil. The boy was not especially ill, and this small white patch on the tonsil disappeared in three days. A culture taken on the first day of the illness, however, contained large numbers of diphtheria bacilli.

Case 23 was that of a boy who had a slight discharge from the nose. There was absolutely no constitutional disturbance, but bacilli of diphtheria were found in the culture.

Case 35 was that of a young lady with a temperature of 104°, pulse 120, having had a chill at the onset of the disease; in fact, the case presented all the clinical appearances of an attack of follicular tonsillitis, but a bacteriological investigation proved the presence of the bacillus of diphtheria. As this case occurred in a family in which there were several small children, if the patient had not been promptly isolated, the results would have been disastrous. In this particular case, it is of interest to note that the bacilli remained in the throat for about four weeks, and also that they retained their virulence, which was proved by the inoculation of guinea-pigs.

Case 38 is of interest from the fact that although there was some redness of the fauces and marked constitutional disturbance, there was no membrane to be seen, but the patient died forty-eight hours after the culture was made in which the diphtheria bacillus was found, with the symptoms of laryngeal stenosis.

In Case 48 the patient had an undoubted attack of diphtheria a month before the cultures were made. At the time of the culture, although the patient was in comparatively good health, there was a slight nasal discharge from which the culture was made. The diphtheria bacillus was found; and in order to settle the question of the virulence or non-virulence of the bacillus, a guinea-pig was inoculated with about two cubic centimetres of a bouillon culture twenty-four hours old. The guinea-pig died at the end of twenty-four hours, and the autopsy showed marked edema of the internal organs. The bacilli of diphtheria were found at the point of inoculation.

The history of Case 51 is as follows: Mrs. B., age forty-seven, had diphtheria three times, the last time about twenty-eight years ago. On November 15th, returning home from a concert, where she perspired very freely, felt chilly, and on the next day had a slight attack of acute coryza, which on the following day was quite marked and accompanied by malaise, headache of a dull character, chiefly frontal, and there was also very slight pain on swallowing. On November 17th there was no membrane to be seen, nor was there any marked congestion of the throat. There was an indistinct swelling about the size of a bean at the angle of the jaw at the left side. On the right tonsil there was a suspicious-looking thin film, covering nearly the whole of the tonsil. On the left tonsil there were several minute points about the size of a pin's head. The film upon the right tonsil, to which allusion has been made, was easily removed. Temperature was 102°, pulse 96. In short, the history of this case and the appearance of the throat would seem to justify a diagnosis of follicular tonsillitis. Cultures,

[1] Read before the Boston Society for Medical Improvement, November 12, 1894.

however, made from this throat, showed the presence of the bacillus of diphtheria. In this case the bacilli continued in the throat for 19 days.

Case 64 is of interest from the fact that on the second day after exposure to diphtheria, before the appearance of any membrane and before there was any marked constitutional disturbance, bacilli of diphtheria were found. Forty-eight hours after the culture was made a membrane appeared.

Case 85 is that of a child eight years old, who had no membrane in her throat, but the culture was taken from a follicular plug. Bacilli of diphtheria were found. The child died eight days after the culture was taken, of laryngeal stenosis, intubation having been performed for the relief of this symptom three days previous.

Cases 88, 89, 90 and 91 are of interest from the fact that the local symptoms were very mild. Diphtheria bacilli were found, and the subsequent history of the cases justified the bacteriological diagnosis of diphtheria.

Case 109 is of interest from the fact that there was a very slight amount of membrane in the throat, and no constitutional disturbance. Bacilli of diphtheria were found in the culture, and disappeared at the end of two weeks.

In Case 116 a soft, yellow membrane, covering the whole of the left tonsil, friable on the surface but adherent at the base, was seen. Temperature 101°, constitutional disturbance moderate. The bacillus of diphtheria was found in the culture.

Case 119 was that of a girl four years old, who had very slight constitutional disturbance. In this case the diphtheria bacillus continued for about two weeks.

Case 128 is that of a young man who had a mild attack of sore throat, who was not ill, but who was in a situation where he must have communicated diphtheria to many people, if the disease had not been recognized by means of a bacteriological examination. The virulence of the bacillus was demonstrated, in this case, by its effect on guinea-pigs.

Case 135 is that of a child who had no throat symptoms, but did have a slight muco-purulent discharge from the nose. A culture taken from the throat was negative. A culture taken from the nose, however, was almost a pure culture of the diphtheria bacillus. In this case the child was not ill. He would have been a source of great danger if he had not been isolated.

Case 138 is worthy of mention because, although there was a slight membrane in the throat, this membrane did not present to the eye the characteristic appearance of a diphtheritic membrane. A culture, however, made from this throat revealed the presence of the diphtheria bacillus.

Case 147 is that of an extremely mild case of sore throat, in which a positive diagnosis without a bacteriological investigation was impossible. Cultures from the throat revealed the diphtheria bacillus.

Case 156. E. R., two and one-half years of age, had a slight sore throat, and also had a suspicious-looking membrane on the arm at the site of a recent vaccination. Very little constitutional disturbance. No membrane in the throat. Cultures made from the throat contained no bacilli; but the culture made from this suspicious-looking place on the arm contained the bacilli of diphtheria.

Case 171 is that of a boy four years of age, in whose throat, twenty-four hours after removal of the tonsils, a membrane appeared; and it became a matter of great importance to decide upon the nature of this membrane. Cultures taken from it proved that it was not of a diphtheritic nature.

Case 180 is a case of purely nasal diphtheria, no membrane having been seen at any time in the throat. There was a profuse nasal discharge, from which almost a pure culture of the diphtheria bacillus was made.

The history of Case 182 has a typical clinical history of acute follicular tonsillitis. Five or six small spots were seen in the throat, but no extensive membrane was found. A culture, however, from this throat contained the diphtheria bacillus.

Cases 202 and 204 are of interest as illustrating the point that diphtheria can be diagnosed by bacteriological investigations before the appearance of any membrane or before there is much constitutional disturbance. In these two cases, as it was known that the patients, adult women, had been exposed to diphtheria, cultures were made from their throats, and the presence of the diphtheria bacillus detected forty-eight hours before the appearance of any membrane.

Case 267 illustrates the importance of a bacteriological investigation where there is a profuse nasal discharge without any constitutional disturbance.

It is unnecessary, however, to cite any more cases.

One very important and interesting point showing the value of a bacteriological examination in cases of diphtheria is the history of 18 cases of nasal diphtheria in which there was very little constitutional disturbance, and in which there was no membrane to be seen. Without a bacteriological examination these cases could not have been recognized as diphtheria. Cultures, however, made from the nasal discharge, proved the presence of the diphtheria bacillus, the virulence of which was tested by its effect upon guinea-pigs.

The following quotation from the report of Dr. W. H. Park, Inspector of Diphtheria to the New York Board of Health of New York City, illustrates the importance of cultures in all cases of a profuse nasal discharge in children. He says:

"A child was admitted into a hospital ward in an anemic condition and with a chronic coryza. Five days later four children in his neighborhood developed diphtheria. Two of these died. In seeking the cause of the diphtheria, suspicion was directed to the child by a slight nasal discharge. Bacteriological examination showed this secretion contained many diphtheria bacilli. On further examination it was found that the child came from a family in which, three weeks before, there had been a case of diphtheria.

"In a family of eight children one child sickened with diphtheria, and a second child, a baby, was sent to a neighbor. The next day cultures showed this baby, as well as two of the other children, all of whom were apparently healthy, were infected with diphtheria bacilli. The three apparently healthy but infected children, as well as the sick one, were at once quarantined, but already one of the family to which the baby had been sent had contracted diphtheria from it."

The cultures from 70 non-diphtheritic throats were examined in order to investigate as to the frequency of the, so-called, pseudo-diphtheria bacillus. Seventeen of the patients were suffering from chronic

diseases of the throat, 15 from uterine disease and the remainder from surgical and medical diseases. In no instance was an organism found that would be likely after a careful examination to be mistaken for the diphtheria bacillus. In these investigations a certain number of bacilli were found, but they were either long slender bacilli, or short stout ones, having no morphological resemblance to the diphtheria bacillus.

In a "Report of the Present State of Knowledge respecting the Etiology and Prevention of Diphtheria," presented on behalf of the English Committee to the Eighth International Congress of Hygiene and Demography at Buda-Pesth, Edward Seaton, M.D., F.R.C.P., says:

"Finally, it must be said that progress in medical preventive work generally (which must obviously include experimental research work) is retarded in a considerable degree by the popular or general conception of the scope of 'hygiene.' This in England has come to have far too narrow a signification. The term hygiene is almost always used to apply to structural works (for example, water-supply and drainage), materials, etc., which, however important they may be as necessary for the prevention of some (so-called) preventable diseases, are apparently useless for the prevention of others, which are also entitled to be called preventable. It will be impossible to combat diphtheria, influenza and other diseases which can only be properly termed preventable when the public and governments understand the necessity for the systematic encouragement of scientific observation and research bearing on the public health, and the furtherance of medical preventive work generally."

In a "Report on the Etiology and Prevention of Diphtheria," presented on behalf of the German Committee to the Eighth International Congress of Hygiene and Demography at Buda-Pesth, F. Löffler, M.D., says:

"(1) The productive agent of diphtheria is the diphtheria bacillus. Dispute as to the etiological definition of this bacillus exists no longer. We can, therefore, henceforth indicate as diphtheria such forms of disease as are infested with the bacillus.

"(2) Not infrequently cases appear in the early stages to the clinical observer as true diphtheria, which, however, are caused by other organisms, as streptococci, staphylococci, pneumococci, and in light or graver form may be mistaken for diphtheria. But the differential diagnosis can be effected through bacteriological research. Statistical compilation on the epidemic spread of diphtheria, as well as on the character of diphtheritic epidemics, cannot represent an exact definition so long as the bacteriological investigation of cases suspected of diphtheria fails to mark a division between true diphtheria bacillus and cases merely resembling diphtheria.

"(3) Diphtheria epidemics show a various character, as do many other epidemics of infectious disease. The course of the epidemics is often very light, but also much more severe, indicated by the high figure of the death-rate, the rapid infection of the larynx and the nose, and by severe heart and kidney affections, and consecutive paralyses. But also in the same epidemic instances of severe and light forms of disease frequently alternate irregularly.

"(4) The variation, of course, will be determined by several factors: (*a*) By difference in the number and the virulence of the diphtheria bacilli; the causes of the latter are not yet absolutely known. (*b*) By concomitant bacteria, and indeed as much by pathogenic as saprophytic. The processes of infection with regard to the diseased mucous membranes in the passages and in the nose appear to influence the course of the disease unfavorably, in part by increasing the virulence of the bacilli, in part by weakening the body through absorption of decomposition product. (*c*) By individual tendencies not yet thoroughly recognized.

"(5) The diphtheria bacilli can appear in the passages, especially of the nose, of separate individuals without causing indications of sickness, which it first induces when it has actually established itself. Lesions of the mucous membranes, small eruptions, catarrhal changes, are favorable to its residence. In brief, meteorological conditions giving admission by the first approach to catarrh (especially cold, damp weather), appear to favor the sickening from this cause. But this influence has to be more closely observed.

"(6) Diphtheria is most rapidly communicated by direct contact between sick and well, through spitting, coughing, sneezing, kissing, and grasping of the hands, whereby the hands come into contact with flesh secretion; also freely through utensils which the sufferer has fouled with his secretions; by beverages, food, eating and drinking vessels, cast-off washing clothes and other articles, as pocket-handkerchiefs, playthings, even long after their actual infection.

"(7) The sick is infectious so long as he has bacilli upon the mucous membranes. The bacilli usually disappear with, or soon after the disappearance of the local signs, but they may be detected still lively and virulent in the passages or nose for weeks and even months.

"(8) On inorganic matters condensed and excluded from light the bacilli can maintain themselves for a period of months; accumulations of dirt, dark and close dwellings favor thus the preservation of bacilli and the extension of disease.

"(9) As a specially noticeable vehicle for the extension of disease is to be noted, the crowding together of susceptible individuals, especially in families of many children. But other gatherings of people, apart from children, where separate persons do not come into such proximity as the members of a family, may offer facility for the extension of infection, as schools, barracks and the like.

"(10) The diphtheria bacillus is so far not identified with certainty as the cause of other diseases similar to diphtheria or of other spontaneous disease of lower animals. The possibility of the conveyance of true diphtheria from sick animals to human beings is thus outside our present knowledge. It is desirable that the governmental investigating committee should combine with research regarding diphtheria coming under their notice the similar diseases of animals, and also the communication from animal to human beings of diseases resembling diphtheria.

"(11) As prophylactic means are to be considered: (*a*) Care for cleansing, keeping dry, sufficient ventilation and lighting of the dwelling; (*b*) careful cleansing of the mouth and nose, gargling with weak solutions of common salt and carbonate of soda, thorough brushing of the teeth, extraction of bad teeth, attention to the deeper cavities of the tonsils, and removal

of hypertrophied tonsils; (*c*) cold douching of the throat in times of diphtheria prevalence.

"(12) Every case suspected as diphtheria must, when possible, be bacteriologically investigated. The physicians must have easy access to the required materials for carrying on the culture, for example, in the chemists' shops. The investigation has to be carried on by specialists, as in the case or cases of suspected cholera.

"(13) All cases proved bacteriologically to be true diphtheria, as well as all cases suspected as diphtheria which have not been bacteriologically investigated, must be dealt with under police regulations.

"(14) Every diphtheria case must be isolated, either in a separate room of the dwelling or in an isolation ward. In order to restrict as much as possible the spread of the bacilli by the sick, a local anti-bacillar treatment must be employed with a view to prophylaxis against the early stages of the disease.

"(15) One of the most effective means against the spread of diphtheria is the protective inoculation, with antitoxin, of susceptible individuals in the neighborhood of the patient, especially of children.

"(16) In every case of diphtheria, disinfection is imperative. This is needed for all utensils for the sick, as well as for the sick themselves and the sick-room.

"(17) Convalescents from diphtheria must not mix freely with others, till bacteriological investigation has proved the absence of the bacilli."

Dr. William H. Welsh, in a paper entitled "Bacteriological Investigation of Diphtheria in the United States," read at the Eighth International Congress of Hygiene and Demography, held at Buda-Pesth in September, 1894, says, "In 752 cases of diphtheria in New York the diphtheria bacilli disappeared within three days after the complete disappearance of the exudate." He also says, and this is a very important point: "A bacillus in no way distinguishable in morphology or in culture, including the formation of acid in bouillon, from the usual diphtheria bacillus, but devoid of virulence, exists. The virulence was tested by injecting into half-grown guinea-pigs one-half to one per cent. of their weight of forty-eight-hour bouillon cultures. This bacillus, although it has been called by some investigators the pseudo-diphtheria bacillus, should not be so designated. It is the genuine diphtheria bacillus devoid of virulence. It was met with in a comparatively small number of cases, out of a large number examined.

"Exceptionally it may occur together with the virulent diphtheria bacillus in diphtheria, and occasionally it takes the place of the virulent bacillus during or after recovery from diphtheria. In several instances it was found in healthy throats. The name pseudo-diphtheria bacillus should be confined to bacilli which, although resembling the diphtheria bacillus, differ from it not only by absence of virulence, but also by cultural peculiarities, the most important of the latter being greater luxuriance of growth on agar and the preservation of the alkaline reaction of bouillon cultures. The pseudo-diphtheria bacillus may render bouillon cultures acid in forty-eight hours when grown anaërobically. The pseudo-diphtheria bacillus in this sense was found in a number of cases, but not frequently. It is probably of different species from the genuine diphtheria bacillus, and is without diagnostic importance."

So far, there have been no investigations to prove that this non-virulent form may not, under suitable conditions, become extremely virulent; and until this point is firmly established it is the part of wisdom to consider this non-virulent form as a probable source of danger.

From the opinion of the authors quoted, and from the results of the 500 cases of suspected diphtheria investigated at the Bacteriological Laboratory, it is evident, that, to accomplish anything in diminishing the frequency of this disease, it is of paramount importance —

First, That in suspected cases of sore throat, or in cases where there is a profuse nasal discharge, a bacteriological investigation should be made.

Second, That in any case of diphtheria the patient should not be removed from isolation until there have been two negative cultures from the throat and from the nose.

Third, That the pseudo-diphtheria bacillus, so called, is not insufficiently frequent to cause any great error in diagnosis.

## REMARKS ON DIPHTHERIA.[1]

BY H. C. ERNST, M.D.

BEFORE there can be had a proper appreciation of the work that is to be presented here this evening, there must be a statement of facts in regard to diphtheria that are now too well supported by experimental evidence to permit any hesitation in their acceptance. There have been certain points in regard to this disease that have been well known for some time, points that later evidence has but brought more distinctly into view. The first and most important, the one that had to be first determined in order to any further intelligent study of the disease, was its cause; and this has been known for years to be a specific bacillus, commonly given the hybrid name of Klebs-Löffler, but properly called the bacillus of diphtheria. Seen first by Klebs in diphtheritic processes in 1883, isolated and described by Löffler in 1884, this peculiar and specific micro-organism has been the subject of many painstaking researches since that time; and the results that have come from these researches have been but confirmatory of the claims first made for it — that it is the actual cause of the process with which it is associated, and that without its presence diphtheria does not exist. This much has been settled for some time; so much so, in fact, that more than two years ago, in writing an article upon diphtheria, I had no hesitation in making the statement that doubtful cases of the disease could only be determined by means of the cultural diagnosis. This opinion was held by others engaged in similar lines of work; but in the study of the subject and of the best cultural characteristics by which this bacillus might be most easily and definitely separated from others similar to it, certain elements of confusion seemed to arise that threatened to obscure the desired precision of results.

The first of these was the presence, recognized by Löffler himself, of the so-called "pseudo-diphtheritic bacillus," a bacterium possessing apparently precisely similar characteristics to the true bacillus of diphtheria, with the extremely important exception that it manifested no pathogenic properties upon inoculation into

[1] Read before the Boston Society for Medical Improvement, November 12, 1894.

guinea-pigs. Evidently this is a crucial point; for any weight that might be attached to a bacteriological diagnosis of diphtheria would be small, if there were any probability that confusion could arise from such a source. For if one were likely to find a harmless bacillus in healthy throats that could not be distinguished from the true bacillus of diphtheria, except by the long process of culture and then of inoculation, the diagnosis of diphtheria by this means would be useless because of the long time it would take. All the best investigations, however, tend to confirm the opinion advanced soon after its first isolation, that the so-called "pseudo-diphtheria bacillus" is not a separate and distinct variety, but that it is merely a non-virulent condition of the true diphtheria bacillus. In any case, whether this be so or not, its occurrence is not nearly as frequent as has been supposed; and as a factor in confusing the bacteriological diagnosis of diphtheria it may safely be neglected, as the evidence to be presented later will show.

Another point that has been urged against the cultural diagnosis of diphtheria is that there are many anginas that are like diphtheria in their clinical course, and that the worst of these are often more severe than the milder forms of diphtheria; they are also undoubtedly infectious in their nature. So, it has been said, what difference does it make whether these processes are produced by the bacillus of diphtheria, or a virulent streptococcus or micrococcus? Of course, the simple statement of such an objection should be its own best refutation; but if that is not enough, it should be recognized that an exact etiology is the foundation of all rational medicine, and in this particular instance that it is of the utmost importance, as the work with the antitoxin of diphtheria shows. For here it makes no difference if the clinical symptoms are exactly the same, the antitoxin is valuable *only* in diphtheria, and is negative or positively hurtful in non-diphtheritic processes. The etiology of those processes similar to diphtheria is a problem aside from that of diphtheria; in this latter we are concerned with the diphtheria bacillus only, and we must determine its presence by the only means known to us.

These two points, then, appeared to be settled, that diphtheria is produced by the diphtheria bacillus, and that examination by culture is the only means of determining whether a given process is the result of its activity or not.

This being true, cumulative evidence was one thing that could be furnished by such an investigation as has been carried on by Dr. McCollom; but other, and, under the circumstances, perhaps more important points were to be determined as well.

Up to the time of the beginning of this research, practically all of the work done upon diphtheria had been carried on in hospital wards, and upon cases that were sufficiently severe to be sent to an institution for treatment. Certainly, in this community, this means that very little information could be gained from these cases in regard to the milder forms of the disease; for the rich do not send their cases to the hospital at all, and the poor do not, until the threatening symptoms force them to take the step. This being so, it was evident that if an attempt were to be made to study *mild* cases of the disease, material must be sought out of the hospital wards. For practical purposes, evidence upon these mild cases was needed; for it was necessary to demonstrate the fact that many apparently mild sore throats occur which are as truly diphtheria as are the most malignant and fatal ones, and that these mild, oftentimes unsuspected, diphtherias may easily be the source from which other and much more malignant and even fatal cases may arise.

To gather information of this kind, one is obliged to turn to the profession at large, for very few, if any, medical men see in their own practice sufficient material of the kind needed to be of value for evidence of this sort. This was done by publishing, a little over a year ago, a letter in the *Boston Medical and Surgical Journal*, stating that information was desired upon this point, and that material would be furnished, instructions given, and cultures made at the laboratory at the Medical School. The response to this letter has been very large, and up to the date of this meeting, there have been submitted for cultural examination almost eight hundred specimens. Most of the work upon these has been completed by Dr. McCollom in person, with, however, valuable assistance from Dr. Burr in obtaining nutrient-materials and completing the examinations when Dr. McCollom's other duties called him away, especially at the time of the smallpox epidemic last winter.

It was thought best, in the beginning, to use the platinum needle rather than the cotton "swab" for securing the material, and to have the nutrient-media inoculated at the bedside; and our experience has amply confirmed the wisdom of the choice. The method is a little more troublesome in the first instance, but the results are more accurate and satisfactory in every way. In the first place, the chances of an excess of material being taken up are diminished, and in the second, the material is at once spread out along the three tracks of the needle, so that an approximation to a plate-culture is obtained, and thus the chances of obscuring the colonies of the diphtheria bacillus by overgrowth are diminished. The main objection to the use of the platinum needle sunk in a glass-rod is the liability of the latter to fracture; but this fault has been done away with by using a metal handle for the platinum wire.

No word of praise is too great for the manner in which Dr. McCollom has carried out the details of the work, which certainly would not have been completed without his persistency and devotion.

## TWO CASES OF SUDDEN DEATH IN CHILDBED.[1]

BY H. W. BROUGHTON, M.D.

I am led to report these cases, first, because they are *fatal* cases. I believe that just such should be recorded, even at the risk of exposing one's errors in diagnosis and treatment, if such exist. Secondly, I report them because of their rarity, for fortunately sudden death in childbed is rare. Moreover, both of these cases present certain features that are more or less unique, at least as far as I have been able to discover after perusing a number of published reports. This is especially true of the second case. Finally, it is a privilege that I appreciate, to be able to address such a Society as this, and to feel that my deficiences will be criticised in a kindly spirit. I am frank to say that I bespeak your forbearance, especially with regard to the first case. This was one of the earlier cases of

[1] Read, by invitation, before the Obstetrical Society of Boston, November 10, 1894.

my medical career, and I wish it had fallen into abler hands than mine were at that time. In fifteen years practice these are the only fatal obstetric cases that I have attended, although I have seen several others in the care of other physicians.

CASE I. Uremic poisoning, with ante-partum concealed hemorrhage, post-partum hemorrhage, eclampsia; death.

Mrs. S., age forty, born in Cambridge. Her mother died at sixty-six of "Bright's Disease"; v-para; several still-born. The mother was very "full blooded," and always before her labors had a tendency to "convulsions," which was relieved by "bleeding." Patient unusually well; married at twenty-two. Had in succession four living children, and then six miscarriages — some at eighth month, others early, at second and third. No known cause for miscarriages. There was no evidence of syphilis. I attended her in the last two. Convalescence was slow, and anemia persisted. She was a woman of large frame, muscles soft and flabby.

Her last pregnancy was uneventful, except that she was anemic and debilitated. At term I was sent for at 10 A. M., and found her in pain. Pain was rather constant, low in front and back, not severe. She was flowing slightly. Blood appeared watery and thin. Although the membranes were firm and unruptured, the os was dilated to the size of a silver dollar, with thick edges. Head could be felt presenting. In two hours I saw her again. She appeared quite pale and weak, and felt somewhat faint. Os fully dilated, membranes still unruptured. A small amount of thin, bloody fluid had continued to flow, and there were two or three clots in the vagina as large as my fist. Suspicious of trouble, I ruptured the membranes, meanwhile giving stimulants by mouth. The head at once engaged; pains became intermittent and natural; and aided by firm pressure over the fundus, a small child was expelled with celerity. The baby was dead, face purple, epidermis easily detached; had evidently been dead for a considerable time. The placenta was at once expressed, accompanied by three or four large clots, each the size of my two fists, and some fluid blood, which was thin and watery. The placenta was very small, friable and more or less degenerated. Uterus contracted well. Ergot was given, and brandy subcutaneously. Patient was very weak, faint and pale, with weak pulse. Heaters were applied, and the head lowered. Brandy and carbonate of ammonia were again given subcutaneously. She gradually rallied, became warmer, and felt a little better. Took nourishment well; pulse improved. Several hours later there was a sudden, single, quite profuse gush of blood, which was immediately controlled by the nurse, who applied pressure over the fundus, and gave ergot. The flow was sufficient to drench napkins and sheets. At 10 P. M. patient complained of great weakness and faintness; body a little warmer. Nurse reported that napkin was wet with urine, but that none could be saved. The only urine that I saw was just before delivery; this was dark-colored, but mixed with discharges, and unfit for examination.

Brandy and ammonia were freely given, subcutaneously and by mouth, with nourishment. Pulse continued weak. There was no edema of face or ankles at this time, and I considered the case one of shock from the hemorrhage, ante-partum and post-partum. The very thin, fluid character of the blood I have already mentioned. I remained through the night. In the morning she was still pale and weak; but there was a little more color about the lips, and she said that she "felt better and stronger." As I concluded afterwards, I believe that at this time there was a slight puffiness about the eyes, but it did not impress me then. The flowing was very slight, consisting of a thin, watery discharge. I left her for a time, feeling that she had rallied sufficiently to justify some hope. At noon I saw her again, and was shocked at the change. The face was very greatly swollen, especially about the eyes and cheeks. The nurse noticed the swelling about 10 A. M., but did not know its import. The bladder was empty. No urine had been passed since the night before. The patient said, "Why do I feel so very weak." She complained of a "choking" sensation in the throat and at the pit of the stomach, which she thought was "wind." The extremities were cold. She asked the nurse to arrange the pillows a little, when suddenly she became ashy pale, and there were marked convulsive movements of the whole face, which lasted for a moment, when she ceased breathing, twenty-four hours after delivery. Body not convulsed at all.

CASE II. Placenta previa, with concealed hemorrhage; death.

Mrs. K. was a reasonably healthy, young German woman, thirty-one years old, of healthy stock. During the past five years she had had four children, and was now pregnant with the fifth since the last of March, 1894. I attended her in three previous labors. They were normal, and she made fair convalescence. In this last pregnancy she failed to notify me of her condition, as she had always done, and had no medical advice. This was unfortunate, for she was not at all well, complaining much of debility, and looking poorly, as her friends report. She "felt life" at the usual time. Fetal movements continued until within two weeks of her last illness, which occurred September 24, 1894, at about the sixth month of pregnancy. This was on Monday. On the Thursday previous she took a long walk, and on Sunday walked to church, and was hardly able to get home, from exhaustion. Sunday night, on "taking off her corsets," she felt pain in the lower part of her abdomen. It felt "as if everything were dropping out." Abdomen "very hard and large." She vomited once or twice. Thought her trouble might be due to "pears" that she had eaten. Pain was continuous all night, although "not very severe." During Monday morning the pain continued, and was a little worse. She could not stir in bed. But they were not alarmed; the husband went to his work. Neither nurse nor physician was notified. She vomited again Monday A. M. About 1 P. M. the pain became much worse; described as a "steady, constant" pain, agonizing in character. She said that she "never suffered so much with all her children." I was called to attend her, and saw her about 2 P. M. The nurse who preceded me by a quarter of an hour, said that she "looked very sick"; with cold extremities "way up to elbows and knees"; ears were "purple" and feet "prickly." Nurse thought that she was going to "have a convulsion." I found the patient in great distress, looking very pale, and with an agonized expression. Pulse weak and quick. Still I have seen the same picture in simple miscarriage. There was nothing objectively to positively alarm one. But her abdomen was hard and tender. She could

hardly move upon the bed, and she complained of a "constant pressing" pain in her back and through the uterine region. This aroused suspicion. There was a slight flow. Os was found to be hard and rigid, admitting only the tip of my finger. I at once etherized, and proceeded to dilate and empty the uterus as soon as possible. I sent for assistance; and soon Dr. J. C. Stedman arrived and gave me, through this most trying case, valuable help. A vaginal antiseptic douche was given (1–3,000 bichloride), and dilatation begun. It was no easy matter to introduce my forefinger through the os; but in time I succeeded. It was grasped firmly by the cervix. Slowly I got the second finger in, when I thought I felt the placenta previa, immediately over the os. I mentioned this to Dr. Stedman. Dark, venous blood now began to flow around my fingers. With three fingers introduced, I could distinctly feel the placental tissue. Blood was flowing freely, dark in color. At length, after fifteen or twenty minutes, I got my whole hand in. The placenta was found to be distinctly previa, lying right over the internal os. It was small and wholly detached, lying loose in the uterine cavity, with a bag of membranes, and a mass of clots above. I pushed through the mass of placenta, clots and membranes, and for a moment the child eluded my search. But I soon found it, lying transversely at the very fundus. I seized a foot, and extracted it promptly, without difficulty. It was ten inches long, and dead, of a dark-blue color. The placenta, and a hatful of clots and fluid blood — perhaps two quarts, followed. The uterus was immediately washed out with hot vinegar and then with bichloride solution (1–5,000). It contracted at once The woman was nearly collapsed, but came out of her ether. In the next half-hour we administered six subcutaneous injections of whiskey, in one drachm doses; ten minims of tincture of digitalis subcutaneously; and two injections of carbonate of ammonia, five grains each, and also one-sixtieth of a grain of strychnia; all subcutaneously. By mouth, one drachm of ergot, whiskey and water freely, coffee strong. Also whiskey and water by rectum. Heaters were applied everywhere about her. Her head was lowered, and the foot of the bed raised. Her hands and limbs were chafed. We fanned her. But all to no avail. She died in half an hour after delivery, from shock and loss of blood.

In briefly reviewing these cases I will simply allude to some of the salient points. In Case I we have a patient whose mother's puerperal career was not without significance, she having had several still-born children, and undergoing venesection before delivery to avert anticipated eclampsia. The patient herself was exhausted by a long series of miscarriages, and late in life, at forty, became pregnant. Nothing is known of the state of her kidneys before delivery; but her urine may have been albuminous, and uremia may have occasioned the death of the child, which had evidently been dead for some time. The hydremic condition of the blood, as evident to the eye, would perhaps strengthen this view. Labor was ushered in not by the normal intermittent uterine contractions, but with a steady, though not severe pain, and with increasing pallor, faintness and debility. Clots were also found in the vagina, which signs are somewhat tardily recognized as diagnostic of concealed hemorrhage. The membranes were ruptured, and the child quickly escaped under the influence of normal pains assisted by pressure over the fundus. This was followed by large clots, and considerable fluid blood and a small degenerated placenta. The patient was in semi-collapse, but rallied a little under free stimulation, when she was again reduced by a profuse gush of blood escaping from the uterus, several hours after delivery. She again slowly rallied through the night, and appeared in the morning, perceptibly though slightly, improved in strength and general condition. Slight edema of face may have been present at this time, but was not observed. By 10 A. M. the nurse noticed that her face was distinctly swollen; and at noon, when I saw her, the edema was extreme. The bladder was found to be empty, a small amount of urine having been passed only once since delivery. Suddenly she complained of weakness and faintness, and her face became ashy pale; she had a slight though distinct convulsion, involving the muscles of the face, and lasting for a moment, when respiration ceased, and she was dead — twenty-four hours after delivery.

With regard to the diagnosis of this case, I should be glad for your judgment. It has seemed to me most probable that uremia was the underlying pathological condition, for the following reasons: The anemic and enfeebled condition of the patient predisposed to it. The dead child, without other known cause, the concealed hemorrhage, the hydremic condition of the blood, the almost complete suppression of the urine after delivery, and finally the edema, with the slight eclamptic attack at the end, all seemed to me to point clearly in that direction. Of course, it is perfectly possible that the death of the child, and the concealed hemorrhage may have come from other causes, and the uremia developed after the birth of the child. As I have said, the other hypothesis seems perhaps the more tenable.

As to the management of the case, it was unfortunate that the patient was not watched during the pregnancy, and the urine examined from time to time. I have most scrupulously since that case, for years, advised that patients report their pregnant condition very early, and send urine for examination, at least once a month. The concealed hemorrhage ought to have been ***suspected*** at least, at the first visit. The absence or diminution in the amount of urine after delivery ought to have been ascertained earlier. Here I was deceived by the statement of the nurse, who reported the napkin wet with urine.

In Case II a healthy young German woman was reduced by five pregnancies in five years. During the last one she was more debilitated than usual, but failed to put herself early under medical care, as she had wisely done in her previous pregnancies. Two weeks before her last illness fetal movements ceased, and at the sixth month, after being utterly fatigued by a long walk, she was seized at bedtime with a steady, persistent pain, and a slight flow and vomiting. She was not seen by a physician until the afternoon of the next day, when she was found in great distress from a concealed hemorrhage. The os was rigid; but it was thought wise to ignore the risk of laceration and to rapidly dilate under ether. This was accomplished with difficulty, and the placenta found to be entirely previa, free and wholly detached. The uterus was promptly emptied of perhaps two quarts of clotted and fluid blood, with the fetus and placenta. The woman came out of her ether, but was in collapse and died in half an hour in spite of stimulation.

I have been at a loss just how to class this case. It was evidently a placenta previa; but the concealed hemorrhage seems to me a very unusual feature. It can hardly be spoken of as an "accidental concealed hemorrhage," as that latter condition seems to be defined as the result of the separation of a normally implanted placenta. Moreover, I have supposed that the term "unavoidable hemorrhage" was applied to the ordinary external hemorrhage of placenta previa. In one sense this was accidental; at least it does not seem to have been caused by uterine contractions, and dilatation of the os. The complete detachment of the placenta seems to me another remarkable feature.

As to the treatment adopted, it seemed to me the only course to pursue in spite of the danger of laceration, and rupture of the uterus. If there *are* any cases of concealed hemorrhage where delay is justifiable this did not seem to my mind to be one. There were two measures that I did not apply to the state of collapse. I allude first to the use of electricity, and second to the subcutaneous injection of a warm saline solution. As to electricity, it may, I suppose, be of service; but the difficulty is that one's battery is never at hand. As to the use of a saline injection, I should be glad for an opinion. I wish I had tried it, although I read of several cases where it was of no avail.

## RAPE.[1]

BY FRANCIS W. ANTHONY, M.D., BRADFORD, MASS.,
*Surgeon to Haverhill City Hospital.*

(Concluded from No. 2, p. 31.)

To consider fully the evidences of rape, it would be necessary to review the normal anatomy of the female genital organs with which I will assume you to be familiar. It is well, however, to bear in mind the various ways that a hymen may appear. Tardieu in his "Attentats aux Mœurs," has collected quite a variety of forms, remarking that there is no universal type. He shows the hymen closed, having a narrow slit, diaphragm with upper opening, diaphragm with central opening, semilunar, annular with irregular edges, with punctate orifice, with double orifice, with double bilateral orifices, with double unequal orifices, with central orifice and two upper parts terminating in a cul-de-sac. Anatomical conditions may be a source of error. Dalbeau describes a vulvar canal just about the fourchette ascribed to indecent assault by a penis too large in a vagina the size of a penholder; Brouardel says perhaps this was true in the case referred to, but such a malformation runs in families, and cites cases to prove his statement. The absence of hymen in an unmarried female is no proof of rape, since it may have been congenitally absent, may have ulcerated away from irritating discharge or scrofulous disease, been destroyed in treatment of vaginal discharge or in medical examination; been destroyed by the female herself or removed by some one else according to her will and with her consent. The presence of the hymen, on the other hand, is no sure proof of virginity, nor that rape has not been committed. It has already been stated that a rape can be committed without the penis reaching the hymen — moreover a woman whom I saw professionally had been married thirteen years to a potent husband and had an unbroken hymen muscular in tissue and guarded by vaginismus; she might have been raped every week, and yet furnished good evidence for the defence. A hymen has been known to persist until the *second* delivery, as stated by Stolz in the *Annales d' Hygiène*, 1873. "Virgines intactæ"!! have frequently required the assistance of accoucheurs and in due time have been delivered of children.

The most important duty that falls to the hand of the physician in a case of alleged rape is the examination of stains which may be seminal.

Suspicious articles received by him should have been sealed and marked for identification. His first duty is to note the time received and the condition of the seal. Having further marked them for his own identification, they should not go out of his direct control until produced, if necessary, in court.

A seminal stain may be simple or mixed with blood, animal fluids or extraneous matter as vaginal mucus, feces, urine, etc.: its color is a shade of gray or yellow, the albuminous matter causes a stiffened feel, the outline is irregular. If fresh, a characteristic odor is present; this is often brought out by moistening and slightly heating, even when the stain is old, and naturally then without odor. The color is best brought out by transmitted light, or, in my experience, by holding the stain a little below the level of the eye in a strong, direct light that thus falls upon it at an angle. This color is more of a gray-brown than the stain of albumen, becoming if the stain is warmed, a characteristic pale-yellow.

There are no reliable chemical tests of the stain. If there is doubt whether the stain be simply albuminous or seminal, Lassaigne recommends that it be moistened with a solution of lead oxide in liq. potassæ at 68° F. when, if albuminous, that is, if it contains sulphur, it turns yellow; while if seminal no change occurs, unless, as sometimes happens, the semen be diluted with an albuminous secretion. Pure seminal stains give no blue reaction with the guiacum test. These tests are only of value on clean, white material. Tidy says to determine if a given stain be seminal, digest it in a watch-glass with a few drops of water for about ten minutes; then place the glass in a good light on a piece of white paper, and add to the solution one drop of nitric acid on a glass rod. If seminal the stain will turn yellow, but there will be no precipitate.

To prepare the stain for microscopic examination, the method advised by C. Robin in the *Annales d' Hygiène*, 1857," and endorsed by Tardieu, is as follows: "A portion of stained cloth is soaked in distilled water feebly alkaline at the ordinary temperature, by holding it by an unstained portion allowing the stain to be in the water. Capillary attraction draws up the water; in a time averaging from three to twelve hours the stain has become smaller and bloated, so that with the point of the scalpel some can be removed and placed upon a glass slide." Tidy recommends that the stain be steeped from thirty-six to forty-eight hours in an ammoniacal solution of carmine; then unravel the fibres of the cloth and examine each one separately in glycerine under a microscope of 500 diameters. Vegetable fibrillæ are not tinted by carmine, while the heads of spermatozoa become a full red.

Wood, in an article to be soon published, recommends that, using great care, the stain be moistened with water or a solution of salt and glycerine; that then it be gently scraped or squeezed. Sometimes better results can be obtained by staining with a solu-

[1] A paper read before the Haverhill Medical Club.

tion of iodine or eosin, while a trace of hydrate of ammonia diminishes turbidity.

For about three years I have employed odd moments in this line of investigation. I find that, in my hands, the best results are obtained by placing the stain over a watch-glass and moistening it with a lukewarm solution of distilled water rendered slightly alkaline by the addition of a few drops of hydrate of ammonia. I take care that the smallest amount of water is used consistent with a little more than saturating the stain. Allowing this to remain a few hours with the stain uppermost, I reverse its position for a half hour, gently moving it in the water. A few drops are then taken up in a new pipette and transferred to a new glass slide. If careful and repeated examination fails to show spermatozoa, I gently squeeze the stain in the water and try again. A long, patient search is often rewarded. Care must be taken to use the minimum of force in squeezing the stain.

A pure seminal stain may contain beside spermatoza, cells and spherical bodies of the seminal passages, pavement epithelial cells of the urethra and cells of the urethral ducts and glands, lozenge-shaped crystals of phosphate of magnesia, granular masses, leucocytes or globules of spherical mucus.

The spermatozoa may be whole or broken. The whole have tadpole-shaped ovoid heads and long tails, and can be mistaken for nothing else. Their length is from $\frac{1}{500}$ to $\frac{1}{600}$ of an inch, occasionally they are not over $\frac{1}{1000}$ of an inch, while the head is about the length of a normal blood corpuscle, $\frac{1}{3000}$ of an inch. Tailless spermatozoa have been described by Dr. H. Gibbes in the *Quarterly Journal of Microscopic Science*, July, 1880.

The presence of spermatozoa is proof positive of the presence of seminal fluid at the spot from which the substance examined is taken, but how gotten there it does not behoove the medical expert to say. In my investigations I am at present at work on a question which I cannot now answer definitely, but which I suggest as an interesting one with some practical legal value, if solved — How far is the size of the spermatozoa, more particularly the length, dependent on the time since the emission preceding the one from which the stain is produced? It seems to me to have, possibly, some ratio.

In the identification of spermatozoa in case of rape Ungar softens the stained material in distilled water to which he has added hydrochloric acid in the proportion of one drop to forty cubic centimetres of water. He has succeeded in obtaining a double staining of the zoösperms by means of eosine and hematoxylon, of carmine and eosine, vesurine and eosine or methyl-green and hydrochloric acid.

The failure to find spermatozoa does not show positively that the stain is not seminal. The fact may be simply that they are not found while still present; moreover, Caspar insists on temporary absence, variation in quantity, and even existence of spermatozoa in the same individual under varying influence, particularly venereal excess. Spermatozoa may be absent in a boy who is still capable of assault, or in an old man, though they probably exist here after the power of erection has gone, or in very advanced years with the power of erection and emission present, as shown by the record of the case previously referred to where a child was born by a woman aged seventeen to her husband aged ninety-two; in which case the "other man" was not suspected. Adult males with old disease of the testis or double gonorrheal epididymitis may have no spermatozoa.

The vaginal mucus should, when possible be examined after a case of rape. Live spermatozoa have been found in the vagina of a little girl fourteen days after she was raped. Their activity is stimulated by alkalies, diminished by weak acids. Temperature above 120° kills in a short time, so that the prolonged hot douche after a rape would be rational treatment.

The only thing liable to be mistaken for spermatozoa are the trichononas vaginæ described by M. Donné as found in the vaginal mucus of an unclean patient; the heads of these are, however, three times as large as those of spermatozoa. They appear to be granular internally, and several ciliæ are apparent. The spermatozoa, on the contrary, are structureless, and have no ciliæ.

Minute ovoid granulations might be mistaken for the heads of spermatozoa, and, possibly, minute fragments of linen fibre for their tails. Some fungi are also said to resemble those tails, but are clumsier and refract light differently. It is safe *not* to give a *positive* opinion except on the presence of whole spermatozoa.

After months of practice, with increasing skill in manipulation and power of observation, I was able to detect spermatozoa in stains of a month's duration, and felt quite elated. Imagine my feelings to learn from an article by Dr. Wood, previously referred to, that Bayard had detected them after six years and Ritter the same, while Rawson had found them after eighteen years.

In examining a supposed seminal stain in a case of rape, watch should be kept for all other objects appearing in the field, especially for fibres of cloth, hair, pus, blood corpuscles, as these may help to fix the crime on the guilty party.

We should bear in mind, also, that a supposed seminal stain is quite possible to have been caused by vaginal mucus, leucorrhea, gonorrhea, lochia, urethral fistula, nasal mucus, meconium, saliva, or foreign matter purposely put in the position found. The stains of vaginal mucus are more apt to be of a yellow or yellowish-green color; those of pus of a green or greenish yellow; all lack the starchy feel of seminal stains.

Everything used in the examination should be new, and so treated that by no possibility can carelessness be charged to the observer. It goes without saying that the duty of the medical expert is to state what he *finds* positively; when it comes to inferences to be drawn from things found, he treads on different ground and needs to use caution. He can often state that, *admitting certain premises*, a certain conclusion must follow, or that a conclusion suggested is not inconsistent with facts found, when a more positive statement might weaken his evidence by having a portion of it discredited; the average juryman not being any too able to distinguish the difference in value between testimony on matters of fact and matters of opinion.

It should be constantly borne in mind that the medical expert is not the prosecuting officer. He should approach the matter with an unbiased mind, by whichever side he may be employed; if the party accused be guilty, he is convicted on the chain made by the links of evidence of which the medical evidence is but a single link, albeit an important one.

I wish to allude to one other matter here. Rape by

a female upon a male, though unknown to English law, is not unknown to French law. It consists of forcible connection by a female with a male, the latter usually a child, and has been followed by conviction.

In considering the question of rape from the psychological point of view, the first thing to establish clearly in one's mind is the normal process of the awakening and growth of sexual desire. Von Kraft-Ebing thus ably summarizes it: "The psycho-physiological process comprehended under the idea of sexual instinct is comprised of (1) concepts awakened centrally or peripherally, (2) the pleasurable feelings associated with them. The longing for sexual satisfaction (*libido sexualis*) arises from them. This desire grows stronger constantly in proportion as the excitation of the cerebral spheres accentuates the feelings of pleasure by appropriate concepts and activity of the imagination; and the pleasurable sensations are increased to lustful feeling by exaltation of the erection centre and the consequent hyperemia of the genitals (entrance of liquor prostaticus into the urethra, etc.). If circumstances are favorable . . . desire is complied with; if the conditions are unfavorable, inhibitory concepts occur, overcoming the sexual longing and preventing the sexual act." This is to my mind the most complete and at the same time compact statement of the psychological and physiological laws governing the matter under consideration that it has been my fortune to read. It will bear careful study, for upon variations from these laws is based all the pathology of morbid sexual conditions.

Most of what immediately follows is taken from or based upon von Kraft-Ebing.

Rape may be caused by physical defects, moral deterioration, each or both, their interdependence being perhaps much greater than is commonly supposed. It is caused by a temporary powerful excitation of sexual desire induced by excess in alcohol or by some other condition. At first it seems improbable that a man morally intact would commit rape; but the question arises, May not his seeming moral defects be entirely due to a perversion of his brain, and hence cause the exclusion of morality as an element in the consideration of his case? For immorality of necessity presupposes and requires a *mens sana* to be capable of balancing right and wrong and executing deliberate choice with freedom of will. "Lambroso (*Goltdammer's Arch.*) thinks that the majority of men who rape are degenerate, particularly when the act is done by old men on children." "For we must remember that a reawakened, perverse, abnormally intense and uncontrollable sexual desire is known to be one of the manifestations of senile dementia." Other causes that often lead to rape are mania, satyriasis and epilepsy. Murder may follow rape; rape may follow murder; murder out of lust is technically called lust murder.

There is a presumption of lust murder when the genitalia of a person found dead are more injured than would be caused by a brutal attempt at coitus. This presumption is strengthened when the body has been opened and the intestines or genitalia are wanting. Lust murders dependent on psychopathic conditions are never committed with accomplices.

In examining an accused person we should consider whether there be a tendency to *cunnilingus irrunare* on boys or girls, *prædicatio puellarum, coitus inter femora*, exhibition, etc., as going to show a degenerate condition. We must bear in mind that the accused may be a "sane man who by satiety of normal sexual indulgence, lasciviousness and brutality, perhaps also by intoxication, has forgotten that he is human."

The most difficult task seems to me to determine where the line of irresponsibility ends and that of responsibility begins. "Education, cultivation, self-control, constitution, organic influences, alcohol, are all factors to be considered."

To my mind a pathological condition, even of a portion of the brain, does not of necessity imply that punishment is injurious to the accused or useless in preventing repetitions of the act. Hysteria has no doubt a pathological basis in the nervous system; and yet, I have seen pain inflicted by me enable its victim to master it. A pathological condition may be strong enough to produce a decided tendency, but the inhibitory concept of punishment to follow is sufficiently strong to overcome this tendency. There doubtless is a point where irresponsibility begins; but to determine this point each case must be taken by itself, and all circumstances, personal, hereditary, physical, mental and moral carefully considered.

The principal cerebral neuroses enumerated by von Ebing as affecting rape are: (1) paradoxia, the sexual excitant occurring independently of the period of the physiological processes in the generative organs; (2) hyperesthesia or satyriasis, abnormally increased impressionability of the *vita sexualis* to organic psychical and sensory stimuli — this may be central as in nymphomania and satyriasis, or peripheral or organic; (3) paresthesia, excitability of the sexual functions to inadequate stimuli — the domain of psycho-pathology.

Examples quoted of paradoxia are the sexual instinct in childhood — due in the male, for instance, to phymosis, balanitis; in both sexes oxyuris in the rectum — and the consequences of masturbation or a neuropathic constitutional condition. A case in the female subject is quoted in Marc's "Die Geisteskrankheiten" (von Adeler). Another instance of paradoxia is the reawakening of the sexual instinct in old age, senile dementia, attempts of the aged upon children — "The intellect may lead to conceive, but the moral sense is missing." "Hyperesthesia may be caused by pruritus, eczema, cantharides, neurosis, hysteria; it may be intermittent or periodic. The diagnosis of paresthesia depends on the investigation of the whole personality of the individual and the original impress leading to the act to distinguish perversion (disease) from perversity (will)."

"The cruelty of rape is but an exaggeration of the aggressive character given by Nature to man to cause the surrender of a woman in spite of obstacles whose overcoming gives him greater pleasure." It is the prize sought for, and gained by difficulties passed, whose possession makes its owner swell with pride. This instinct carried to excess, causes anthropophagy, as exampled, perhaps, in the Whitechapel cases. The desire to inflict pain and to use violence is termed sadism; its counterpart is mesachism, the desire to suffer and to be subjected to violence. "These are the fundamental forms of psycho-sexual perversion, which may make their appearance at any point in the domain of sexual alienation."

I have endeavored in this paper to set forth enough of the — to me — interesting matters arising in connection with a question which at first sight seems sim-

ple in the extreme, as shall cause you, if ever called upon to deal with a case of rape, to do at the same time justice to the victim and, none the less, justice to the accused. The manner in which such an apparently simple subject leads one through the domains of law, of psychology and of medicine, with their allied branches, is but another proof of the fact we are having impressed upon us every day — the profession we have chosen and which we love is one that, while it renders the task difficult by occupying our time in other and important ways, demands of each none the less imperatively a continual research in every direction, that we may fit ourselves thoroughly for the solemn duties of our lives. And herein lies the charm; work as we will, study as we will, the field is still broad, and never can we say, even if our time is devoted to a special branch alone, we are masters of every detail.

## Clinical Department.

### A MECHANICAL TREATMENT OF ECZEMA IN YOUNG CHILDREN.

BY HERBERT J. HALL,
*Interne at the Children's Hospital, Boston.*

Authorities in dermatology will doubtless agree that the application of ointments and pastes is only the beginning of the treatment of eczema. Whatever the type or distribution of the disease, after a wise choice of medicaments comes the greatest difficulty, the prevention of scratching. No matter how carefully the hands and feet may be tied, the child will occasionally get free. The greatest danger is at night when constant watching is not practicable. Tight bands at the wrists and ankles are objectionable, and

they must be tight to hold the child. Let a child feel that he is held so that he cannot move, and a desperate resistance at once begins which will usually end in an aggravation of the disease. In spite of obvious defects, the "pillow-case method" has been considered the best up to the present time. The child is put into a pillow-case and the open end is gathered about his neck. The legs are abducted and sewed in by means of seams on each side, close to the legs. The arms are placed a little way from the body and treated in the same way. The edges of the pillow-case are then pinned to the mattress of the bed. The arms and legs of the child are thus allowed a certain amount of harmless motion, but he must lie flat on the bed and the back is sure to perspire in hot weather. In this method, also, the head is free and the child may rub his ears on the pillow. It is a matter of common observation that eczema of the ears is hard to cure, and this is largely because the child harrows up the skin by rubbing on the pillows at night.

The original suggestion for a new treatment, which I will call the hammock method, was made by one of the Sisters in charge of the wards at the Children's Hospital. Take a stout piece of duck a little longer than the child, and about two-thirds of a yard wide; turn up an inch at each end, and stitch it down for the admission of a straight piece of iron as wide as the cloth, and stout enough to support the weight of the child. These iron rods are the spreaders, and should have a ring at each end for cords, which are pulled tight and fastened to the posts at the head and foot of the bed. We now have a duck hammock stretched tightly over the bed, with a good air-space between it and the mattress. Four many-tailed bandages long enough to include the whole arm or leg are sewed to the hammock in the lines which would be taken by the arms and legs when slightly abducted. The child is placed upon his back on the hammock, ointments are applied on soft cloths, and the arms and legs secured by smoothly tying the many tails. In the canvas on each side of the head a square window is cut, leaving the head supported by a strip perhaps four inches wide. A turn of bandage over the forehead and under this narrow strip prevents the head from being raised. The head can be turned from side to side with considerable freedom, but if the windows in the hammock have been properly placed, the ear finds nothing to rub against and will remain uninjured no matter how violent the twisting of the neck. To complete the apparatus, a small bell is tied to the side of the hammock, so that any unusual struggle for freedom will attract the attention of the nurse.

A sufficient trial of this apparatus has been made at the Children's Hospital to warrant the claim of the following advantages:

(1) Comfort. There are no tight bands, the many tails giving firm but uniform pressure throughout the length of the limb. No part is overheated. The child does not feel restraint, because a good deal of harmless motion is allowed by the play of the hammock.

(2) The danger of scratching is reduced to a minimum, and the ears are especially protected.

(3) Applications are easily made and changed.

(4) Simplicity and cheapness of construction.

## Medical Progress.

### REPORT ON DISEASES IN CHILDREN.

BY T. M. ROTCH, M.D., AND A. H. WENTWORTH, M.D.

#### GASTRO-INTESTINAL SEPSIS.[1]

The works of Widerhofer, Parrot, Epstein, von Hofsten and others have established the fact that the varieties of acute enteritis occurring in the nursing infant, differ when observed in hospitals and in private practice.

1 H. Fischl: Jahrb für Kinderheilk, 1894, xxxvii, p. 288; abstracted in Revue Mens. des Maladies de l'Enfance, November, 1894, tome xii.

Fischl, who has studied the lesions in these cases for a number of years, has been impressed by observing clinically, apparently mild cases which have caused severe lesions of the mucous membranes, and, on the other hand, cases of the utmost severity, in which the lesions were very slight. These apparent contradictions have been explained by the bacteriological examinations. The works of Epstein, Cholmogoroff, Gartner, Gaston, Neumann, von Puteren and others have thrown much light upon the different places of entrance of infection in the new-born.

Epstein has shown that in certain cases the infection can be disguised in the form of an acute enteritis, a fact which is not generally known.

Fischl has examined histologically and bacteriologically 21 cases in Epstein's clinic in which the diagnoses of atrophy, debility, septicemia and gastro-enteritis, the latter in 11 cases, have been made during life. Eleven cases were simply examined microscopically, and in these the organ chiefly invaded by the organisms was the lung. In the remaining 10 cases the examination was completed by the bacteriological examination of the blood taken from the heart, and the other organs were subjected to trituration, and cultures made from the triturates. In these cases he found that when the cultures taken from the lungs gave positive results, the cultures made from the other organs gave the same results. In seven of these cases he found the staphylococcus pyogenes albus. Four of these seven cases had the symptoms of acute gastro-enteritis; the other three had the symptoms of septicemia. In only two cases could he find a suppurative omphalitis. In the remaining cases he only found at the autopsy the lesions of acute gastro-enteritis. The staphylococci were very virulent. In a case characterized by the appearance during life of numerous abscesses in the lungs, the cultures showed the staphylococcus albus and aureus. Finally, in the last two cases examined bacteriologically, he found the streptococcus pyogenes once alone, and the other time associated with the coli bacillus, the latter were localized in the spleen and were not virulent.

The researches in question have shown the existence of micro-organisms, pyogenic and virulent, in the organs of individuals who have succumbed in some cases to acute gastro-enteritis and in others to septicemia. This fact, according to the author, shows that at least a certain number of the cases of acute gastro-enteritis which one observes in hospitals are only a manifestation of acute septicemia.

The anatomical lesions which one finds in the various organs are the following: In the lungs the lesions can present themselves in three forms. Most frequently one finds foci which have been incorrectly designated as inflammatory. In these cases the process consists in a degeneration of the alveola epithelium, causing them to swell and their nuclei to stain imperfectly. After this they are desquamated, and fill the alveoli in such a way as to simulate an inflammatory process. In other cases, in addition to the desquamation of the epithelium, one finds the edges of the alveoli infiltrated with leucocytes which often invade the walls of the bronchioles and advance under the epithelium, as in syphilitic interstitial pneumonia. That which bears witness in these cases to the septic origin of the lesions is the frequency of hemorrhages of which the foci are sometimes sub-pleural, sometimes inter- or intra-alveolar. The micro-organisms are sometimes found at the limits of the lesions as veritable agents of propagation, sometimes in the centres of abscesses and sometimes in the walls of the bronchi, or in the centres of alveoli. They are rarely found in the blood-vessels, but they often fill the lymphatics.

The gastro-enteric tract presents the lesions of gastro-enteritis; but often in spite of the severe clinical symptoms one finds only an intense hyperemia which is perhaps the result of the action of the toxine on the vaso-motor nerves. The micro-organisms are very variable on the surface; but when the epithelium is intact they are found neither in the interior of the cells nor beneath them. Neither are they found in the blood-vessels or lymphatics. When the infection is very severe, a few are found in the mesenteric glands. The liver shows frequently cloudy swelling of the epithelium, but micro-organisms are rare.

In the kidneys lesions of the epithelium are constant in the convoluted tubules, and frequently hemorrhages either sub-capillary or in the glomeruli. Quite often there are miliary abscesses with masses of staphylococci at the junction of the cortical and medullary portions of the kidneys. In other cases the micro-organisms are lodged in Bowman's capsule.

The spleen, which is not always enlarged, presents sometimes a simple hyperplasia, sometimes hyaline changes of the reticulum and of the adventitia of the arteries. The micro-organisms are almost as constantly found in the spleen as in the lungs. The pancreas and salivary glands sometimes show parenchymatous degeneration of the epithelium.

In general, the lesions do not seem to vary with the nature of the infection, but too few cases have been observed to base a definite judgment upon. One thing is shown, namely, that in the cases which are clinically different one finds identical anatomical lesions, suggesting the action of a septic virus of which the special organism can be discovered in certain cases. The places of entry of the infection are variable and difficult to locate precisely. By the side of certain cases where one finds a lesion of the buccal mucous membrane sufficient to be considered as a place of entry, there are other cases in which the mucous membranes are normal.

The infection through the air certainly plays an important part, as shown by the frequency and severity of the pulmonary lesions, by the appearance of suppurative otitis, and by the large number of cases which occur in the winter and spring. In all the cases the infection through the alimentary canal seems to play a secondary part. Cases of infection with gastro-enteric symptoms have been observed in the new-born fed during a few days with an infusion of tea.

In closing, the author cites the works of Sevestre, Renard, Girode, Lesage, Marfcon et Nanu; the work of Meyer who mentions cases of death of the new-born from umbilical arteritis, and found streptococci and staphylococci and the anatomical lesions similar to those which occurred in the author's cases; the work of Strelitz, who found the streptococcus pyogenes in a case of Winckel's disease; and that of Neumann, who isolated the staphylococcus in a case of hemorrhagic diathesis, etc.

### THE HEMORRHAGIC DISEASE OF THE NEW-BORN.[2]

The hemorrhagic disease of the new-born is studied by Dr. C. W. Townsend in an analysis of fifty

[2] C. W. Townsend: Archives of Pediatrics,, August, 1894, p. 559.

cases, which he has grouped together under the title given above, owing to the presence of certain characteristics common to all the cases. These are, the general and not local nature of the affection, its self-limited character, and the presence of fever. These, together with the greater prevalence of the disease in hospitals, would suggest an infectious character. Thus 45 of these cases occurred in the Boston Lying-in Hospital, making about two-thirds of one per cent. of all the cases; while five cases only, occurred in the out-patient department, or one-tenth of one per cent. The general character of the disease is shown by a table giving the various sources of the hemorrhages, which include the gastro-enteric tract, the various cavities and the skin. Although bleeding from the umbilicus occurred in eighteen cases, in only three was it unaccompanied by hemorrhage elsewhere.

The self-limited character of the affection is shown by the fact that in all cases, the bleeding began within the first week, or at the latest within the first two weeks of life, and all went on to death or complete recovery within five to nine days.

The distinction between this affection and true hemophilia is insisted on, the latter rarely showing itself in the first year of life, being not self-limited and occurring much oftener in females, which is not the case in the infantile affection.

The temperature charts are of interest, and show a preliminary rise to 102° or 103°, followed by a subnormal temperature as a result of the loss of blood. A test for the recognition of disintegrated blood in the stools is given (Teichmann's test), and the results of post-mortem examinations.

For treatment it is important to remember that the disease is self-limited and not necessarily fatal — 62 per cent. in Dr. Townsend's cases. Perfect quiet, careful feeding with a spoon or dropper, warmth in the stage of collapse and alcoholic stimulants even in the stage of bleeding, are recommended.

### PATHOLOGY OF RHACHITIS.[3]

The very first signs of rhachitic disease in the infant are always found in those parts of the bones which are in the most active stage of development.

In the first days of extra-uterine life, it is the skull which undergoes the most marked physiological changes. Rhachitic disease of the skull attacks preferably two regions: the occiput, extending into adjacent parts of the parietal bones; secondly, the borders of the anterior fontanelle.

The author divides the skulls of the newly-born into three different classes: first, those in which all the fontanelles, with the exception of the large one, are closed, the cranial bones are in firm juxtaposition with no defects in their development. The second group consists of skulls, the bones of which are still very movable and often overlap each other. The third group includes those cases in which we find all the changes present which at a later period in the development, we would call a true craniotabes. Now the question arises, how far the conditions of the third group are physiological and how far pathological, or can we draw a sharp line between the physiological and very early rhachitic disease. To solve the question, the author examined 1,164 children and found 34.6 per cent. had craniotabes. The higher percentage was obtained in those under three months of age; it decreased steadily up to the first year when there was an abrupt fall in the percentage to less than one-half of the preceding three months. During the second year, the cases of craniotabes diminished rapidly, but a few sporadic cases were still met with in the beginning of the third year.

The rhachitic changes in the cranial bones range from simple softening which can only be detected by the most careful palpation, to the total destruction of the bone, in which the latter presents itself as a soft pulpy mass; along the borders the bones undergo changes, which mark the degree of severity of the disease; from the simple softening of the border, to absorption of the bone, sufficient to cause a gaping of the sutures up to a finger's breath. The sagital suture is most frequently attacked. A further sign of craniotabes is the long-delayed closure of the small and of the posterio-lateral fontanelles; in the majority of the newly born these fontanelles are almost entirely closed. Another characteristic sign of early craniotabes is the softening of the borders of those bones which go to make up the large fontanelle. This condition of the bone is always pathological and never physiological, as formerly claimed; furthermore it is claimed by the author, that in healthy children the closure of the large fontanelle is a continuous process from the first day of extra-uterine life, and not, as claimed by Elsaesser, that the fontanelle enlarges up to the ninth month, after which it begins to close. How is it in rhachitis?

The author differentiates three modes of closure of the large fontanelle: first, it may follow the same rule as in healthy children, that is, it grows smaller with age; secondly, it may remain unchanged for a shorter or longer interval and then diminish in size; or, thirdly, it enlarges primarily, and then after remaining stationary for a time, closes. The average size of the large fontanelle in rhachitic children is, even in very early life, far greater than in healthy ones, and the closure may be delayed until the second half of the third year; any enlargement of the large fontanelle is always a pathological condition, and if not due to hydrocephalus, is always caused by rhachitis.

It is the first year of the infant life in which these changes of the large fontanelle take place, but in some cases the disease undoubtedly started in utero. Craniotabes is usually found in all these cases, but there are some in which the above changes of the large fontanelle may be the only symptom of rhachitic disease. Another very important symptom of early rhachitis is the change found at the junction of the ribs and their cartilages, the so-called rhachitic rosary. It often requires a very careful examination to find this sign in less pronounced cases. Rhachitis is by far a more frequent disease than the older writers would lead us to believe. It requires a careful examination and careful observation of our little patients to reveal the less marked signs of the trouble.

In Berlin, the author found out of 1,303 patients, 858 had rhachitis, a proportion of 65.8 per cent.; among 498 children under six months of age, 313 were rhachitic, or 62.8 per cent; showing that the disease may start in very early life, and rhachitis congenita is by no means rare. The congenital form usually manifests itself in changes in the cranial bones.

As to the climatic influence on the disease, the author has found that there was a marked fall in the proportion of the affected during the summer months,

[3] Cohn: Pathology of Rhachitis, Jahrbuch f. Kinderheilk, Band xxxvii, Heft 2, abstracted in Archives of Pediatrics, August, 1894.

which is explained by the changes in the hygienic surroundings of the patients.

Rhachitis is always a constitutional disease, and its manifestations may be divided under two headings:

(1) All the various affections of the bony skeleton.

(2) The disturbances in the nervous system.

One or the other of these may be especially pronounced, or both be equally well marked.

The enlargement of the spleen has not been as frequently met with as claimed by Kuttner.

In the therapeutics the author does not give anything new; good hygienic surroundings are the cardinal indications. Phosphorus, which, according to Kassowitz, is a specific *sine qua non*, has always been of benefit and particularly in the cases which show marked disturbances of the nervous system.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

JOHN T. BOWEN, M.D., SECRETARY.

REGULAR Meeting, November 12, 1894, the President, DR. C. F. FOLSOM, in the chair.

DR. C. B. PORTER showed a specimen of

MYOMA OF THE UTERUS,

weighing thirteen pounds, removed by abdominal section.

DR. J. H. MCCOLLOM and DR. H. C. Ernst read papers on

THE IMPORTANCE OF BACTERIOLOGICAL INVESTIGATIONS IN CASES OF DIPHTHERIA.[1]

DR. S. H. DURGIN: I have been asked to say a word about the recent appointments and plans of the Board of Health for the inspection of schools and the care of contagious diseases. I would say that I have been very much interested in the papers, and I consider the bacteriological work an excellent part of the plan which has been laid out for the suppression of diphtheria.

It is well known that for many years diphtheria in Boston has been practically endemic, but in the last few months it has increased so much as to possibly bear the term epidemic. In September diphtheria increased considerably, in October very much more; and so far during the present month it has increased faster than it did previously. I have drawn from our records the number of cases and deaths which have occurred each week since the first of September, 1894, and find that in September there were 236 cases, with 72 deaths; in October 367 cases and 105 deaths; for the first ten days of November there were 266 cases, an equivalent of 798 cases for the month should it go on at the same rate, and with 58 deaths; a total for ten weeks of 869 cases and 235 deaths, and a percentage of deaths amounting to 27, which, by the way, is not large, and if we take into account the fact that many cases exist without being reported the percentage would be still lower. There are many mild cases which do not come to our knowledge, while practically all deaths are reported. With this increase, with the alarmed feeling in the public, the Board of Health has been enabled to put in operation a plan which it matured and tried to inaugurate three years ago. We have appointed fifty physicians, divided the schools into fifty districts, and placed one physician in charge of each district. Their duties will be to visit each school every day soon after the beginning of the morning session, and see the teacher, who will bring to the attention of the physician any case of illness that may be noticed in the school. The physician will make an examination of the child and advise the teacher whether or not to send the child home, and make a record of the facts. Another duty for the officer, is to visit each case of reported scarlet fever or diphtheria in his district each day, the Board of Health sending to him each morning a list of all the cases of diphtheria and scarlet fever occurring in the city, with their location, so that each officer will be able to pick out those cases which are to be found in his district. He will visit the family of the patient simply to see whether or not the order of the Board of Health as to isolation is being carried out, and report the facts to the Board of Health. He will also at the termination of the disease report to the Board of Health the fact; and in cases of diphtheria that report must be based upon a bacteriological examination which has shown that the diphtheria bacilli were absent; then the Board of Health will issue its certificate for the release of the patient and the disinfection of the house.

I hope it will not be understood by the physicians that this is intended to interfere with any of their prerogatives; it is rather intended to relieve them of many unpleasant importunings for the release of patients from isolation before it is safe to do so.

It is the purpose of the Board to relieve you of that duty and narrow down the responsibility to a small number of officers whom we shall hold responsible for certificates of complete recovery in cases of scarlet fever and diphtheria. The return of children to school is a subject for subsequent consideration; and we do not propose to interfere with the exercise of the statute law which requires that no child from a household in which there is a case of small-pox, scarlet fever, diphtheria, etc., shall attend school until two weeks have elapsed after the recovery, death or removal of the last case of the disease, and that that fact shall be certified by the attending physician, or the Board of Health. Certificates of recovery, for disinfection and school attendance have been given carelessly, and it would be an unpleasant duty to reject one and accept another physician's certificate. I have seen a mother with a certificate of recovery in one hand and the desquamating child holding the other hand, in the health office down-town asking for disinfection. Many children have gone back to school while desquamating from scarlet fever, and many children have gone back into school while Dr. McCollom's examination would show the presence of the diphtheritic bacillus; and it is a fact well known to all of you that one of the great causes of the unreasonable presence of diphtheria in our city has been from children convalescing from diphtheria and scarlet fever in the streets, in the schools, and elsewhere out of isolation. It is with the view of holding these children in isolation, until such time as they can no longer convey the disease to others, and to correct an improper and dangerous school attendance that we have instituted this new work.

[1] See pages 49 and 52 of the Journal.

We have not quite completed our arrangements; but there will be in every part of the city a station in which culture-tubes will be lodged, and all physicians are invited to make use of them, to make the cultures as suggested by Dr. McCollom. They will be sent daily to the Harvard School Laboratory and there examined; and at the end of twenty-four hours a word returned to the physician as to the result. I have also prepared, and it will be sent out to-morrow, a list of all the cases of diphtheria and scarlet fever that have occurred in Boston during the month of October, for the use of the physicians who have been appointed in the districts. One of the drawbacks which face us at the present time is the want of hospital accommodations. The new wards of the City Hospital which are now being prepared for this purpose will not be ready under two or three months. If we had the hospital room we would at once remove many cases of diphtheria which are now spreading the disease for want of possible isolation.

DR. F. H. WILLIAMS: I have been very much interested in what has been said this evening; and it seems to me that we cannot do too much to attempt at least, and I believe it can be attempted with success, to lessen the amount of diphtheria which we have in our community. Two years ago I began making the bacterial tests on patients with membranous throats, and for nearly two years they have been made regularly in the pathological laboratory of the City Hospital. During that period I have read three papers on the subject of diphtheria, and perhaps what I have to say will be simply a repetition; but as the subject is important, you will pardon me if I rehearse some of the points which need to be emphasized frequently. I think it is well to bear in mind in the first place the natural history of this disease. First you have the bacillus in the throat. This stage may last for some hours, or for a number of days, and then is followed by congestion, and later, usually, by false membrane. One cannot tell with certainty whether it is a case of diphtheria or not in the first stage without the bacterial test, nor in the last stage after the membrane has disappeared from the throat. The bacilli may remain in the throat for weeks or months. I recall a case where the bacilli remained one hundred days from the time that the disease was supposed to have begun, and these were dangerous bacilli that were capable of infecting healthy persons. The bacterial test is indispensable during the first stage, when there is nothing to be seen. Let me cite a case that occurred in a family where there was diphtheria. A swab was taken from the apparently normal throat of an individual who had been much in contact with the patient, and she was then sent to a laryngologist who reported that there was nothing to be seen in the throat. Thirty hours after this examination the membrane appeared, and it proved to be a very severe case of diphtheria. The swab had detected the bacilli in the throat before there was any other evidence of the disease.

As regards the prevention of this disease. It is spread, of course, in various ways, but I am inclined to think chiefly by being transferred from mouth to mouth or from hand to mouth or hand to nose. Another point, and one which so far as I know is a new one, is to have the bacterial test applied to all the members of a household in which there is a case of diphtheria. I made this a rule some time ago. In a family with several children, one having diphtheria, you are quite likely to find within a few days or weeks that some of the other children develop the disease; and the same is true in a school, or where any number of children are together, and for that matter also adults. Roughly estimated, I should say that in most of the families I have examined thus far I have found wholly unsuspected cases of diphtheria, so that the first thing to do after discovering a case of diphtheria is to have the bacterial test applied to all of those who have had any chance of getting the disease; then we shall be able to know early when the patients have it, and take suitable precautions and treat them early. If the disease is treated early locally, except in very young children, the patients usually recover.

As regards the trustworthiness of the bacterial test. Although those who have had experience with it are inclined to advocate it warmly, I think we should remember that it is not infallible. Up to the present time the bacterial test has been applied to something over five hundred of my patients. Now, at times, the test does not detect the bacilli when present. That is not common, and I do not make this statement to discourage any one from having belief in the test and using it as much as possible, but the test may have to be repeated two or three times before the bacilli are found, and sometimes even then does not show them. These cases, I think, are rare. I recall one case where cultures were made with negative results but I believed it to be a case of diphtheria. A swab was taken from a piece of false membrane and examined with negative result. Then a bit of sterilized cotton was rubbed over the membrane, put on a cover-glass and stained without waiting for growth in the culture-tube and the bacilli were readily detected. They were just as characteristic as you get from the culture-tube.

What Dr. Durgin said about the increase in the disease reminds me that October, November, December and January are the four months in the year during which the mortality from diphtheria in this State is greatest, so that we are in the midst of the diphtheria season.

DR. R. H. FITZ: I have been much interested in listening to what has been said this evening, and especially the evidence which has been brought out by Dr. McCollom. We are all deeply impressed with the communications made at the recent Congress in Buda-Pesth, not only with reference to the recognition of diphtheria and to the precautions to be taken against its spread, but also with reference to the treatment of this disease. The uncertain progress of sore throats is so evident that it has been my custom for a number of years to look upon all such cases with a considerable degree of suspicion, and to advise isolation if there is the slightest reason to consider them as deviating from the ordinary course, especially if particularly severe or suggestive of the formation of a membrane. It would seem as if this precaution could not be too distinctly borne in mind, especially by physicians who have not the facilities which the city offers for bacteriological investigation. Certainly they would err on the right side; and there seems to be a growing reason why cases of even apparently simple sore throat should be isolated for a few days, like doubtful measles or scarlet fever. At the same time we must remember that diphtheria bacilli may be found in throats of persons who show no symptoms

of diphtheria, and that there are cases of the prolonged retention of diphtheria bacilli in the throats of patients who have long been free from symptoms. Hence, it is evident that the mere presence of the diphtheria bacillus is not sufficient to make a diagnosis of diphtheria, and that persons need not be necessarily frightened because diphtheria bacilli are found in the throat. It is, however, very important to recognize the fact that if such individuals do not suffer directly from the disease, they represent vehicles of contagion, and that persons exposed to contact with them may suffer in the severest possible way. It is to be hoped that Dr. McCollom will continue his investigations with reference to this class of cases, that is, healthy persons who have no symptoms of diphtheria, and who for a longer or shorter time may harbor these bacilli in the throat.

A point Dr. Durgin has mentioned with reference to the mortality in the present epidemic is interesting. He says the total number of cases of diphtheria is not represented by the figures in the possession of the Board of Health, but a great many unsuspected cases exist; hence, the mortality may appear unduly excessive from the large number of unreported cases. I was interested in this statement because there arrived to-day the latest information from Koch's laboratory and hospital, with reference to the mortality of diphtheria treated by the serum method, according to which only about 16 per cent. of the cases thus treated are fatal. This gives evidence that of the cases which are sufficiently severe to be brought into the hospital for treatment, the mortality is represented by that figure. On the other hand, the statement is made that no death occurred among cases of diphtheria brought under treatment in the first two days of the disease, at which time they are probably to be regarded as mild cases. Certainly it is a great advantage to be able to recognize a possible or probable case of diphtheria before any symptoms of severity appear, and in case the serum treatment continues to hold the position it now assumes, by an early recognition to reduce enormously the mortality.

DR. DURGIN: Dr. Fitz mentions the interesting fact that many of the cases of apparent tonsillitis might prove to be diphtheria if properly examined, and expresses the hope that Dr. McCollom will continue these investigations. I neglected to say that there is and will be the broadest invitation possible to the physicians of Boston to make use of these culture-tubes with the slightest suspicion that you can have in case of ordinary looking tonsillitis or sore throat. If you have any doubt whatever, you are invited to take these tubes, make the culture, and leave it at a station. You merely have to take the tubes from the station, return them, and get more tubes. I will also say that Dr. McCollom has been relieved from all other duties and assigned to the excellent work which he is now doing with Dr. Ernst, who has also been given such additional help by the Board of Health, as he has asked for, to carry along the bacteriological work.

DR. E. M. BUCKINGHAM: I entirely agree with Dr. Williams that diphtheria is conveyed by actual contact, either direct or indirect, and to no appreciable extent through the air. Both clinical and bacteriological evidence, so far as I know them, point in this direction.

DR. F. I. KNIGHT: I am sorry not to have heard Dr. McCollom's paper. I want to say one word in regard to the value of bacteriological investigation of the patient after recovery, in deciding when he shall return to his ordinary avocation and associate with the family, etc. It seems to me that although this is a good thing, too much value ought not to be attached to a negative result of the examination, for the reason that the region from which the cultures are taken is so limited, and there is such an opportunity for remaining disease in the posterior nares and in the inaccessible parts of the upper air-passages.

DR. WILLIAMS: If I may be allowed one word more, I would like to say that you may find cases of diphtheria where nothing appears in the throat, and in a few days the baccilli disappear. On the other hand, as regards what Dr. Knight said, we must be very careful not to rely on one negative report. I think it is well to say that all methods of treatment are much more successful if begun early — either the serum treatment or the local treatment. The local treatment, which has been used by Löffler in 96 cases, three-quarters of which were diphtheria, was very successful indeed; all recovered. In the cases I treated with strong hydrogen-dioxide solutions, which I saw early in the disease, the mortality was less than ten per cent.

DR. F. W. DRAPER: I am glad of an opportunity to testify how heartily in sympathy I am with all that has been said to-night. What has been said has been progressive and reassuring — progressive because it shows that our teachers are alert and abreast with the latest scientific researches; and reassuring because we have had a demonstration that is distinctly in the line of preventive medicine; and it seems to me that not only the profession, but the entire public, should recognize that fact and be truly grateful for what has been done with such success. I hope the example set by the City Board of Health will be followed by local boards of health elsewhere; and I trust that the State Board of Health will also take up this kind of work and aid in measures from which the public will benefit.

DR. ERNST: One thing I would like to call attention to. It seems to me that one of the most important points shown by this work of Dr. McCollom's is the fact that in no single case where the bacilli of diphtheria have not been found has there been any indication of diphtheria occurring in that patient afterwards, so that the probabilities are that there is some other explanation of the failure of bacilli to grow in the cases collected by Dr. Williams. The special point we have been trying to make is that the method of diagnosis is trustworthy.

DR. H. E. MARION: I have to show the

### CLINICAL CHART OF A CHILD WITH MILD TYPHOID FEVER.

The highest temperature reached 105°. The pulse never reached above 60; the lowest and *normal* pulse of the child was 35. It is a case of brachycardia. The boy, fifteen years old, has been under my observation since infancy and this (35) has been his normal pulse.

---

GASTROSTOMY IN A YOUNG CHILD.— At the meeting of the Société de Chirurgie at Paris, December 19, 1894, Dr. Monnier presented a child five years of age upon whom he had done gastrostomy for an impassable stricture of the esophagus due to swallowing caustic potash.

## THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

Regular Meeting, November 10, 1894, the President, Dr. Charles M. Green, in the chair.

Dr. H. W. Broughton read, by invitation, a report of

### TWO CASES OF SUDDEN DEATH IN CHILDBED.[1]

Dr. J. B. Blake referred to a case reported by Dr. F. B. Harrington and the late Dr. Strong, where the patient on the point of death from hemorrhage was saved by a large intravenous injection of saline solution.

Dr. C. E. Stedman said that the writer was particularly to be commended for reporting fatal cases, as these are often much more instructive than successful cases. The subcutaneous injection of saline solution has been found of great value and is much easier to perform than intravenous injection.

Dr. A. Worcester referred to a case where a physician saved a case of post-partum hemorrhage following placenta previa by pumping a large amount of salt solution under the skin by means of an aspirator. The water thus injected is rapidly taken up. The amount of water which is taken up by the digestive tract in these cases is astounding. Hence it is reasonable to give water by the mouth as well as the rectum.

Dr. G. D. Hersey, of Providence, especially commended the use of saline solution by the rectum.

Dr. C. M. Green reported briefly a case of placenta previa with hydramnios which he had recently had at the City Hospital. Here he delivered promptly, and the patient made a good recovery.

## Recent Literature.

*On Chorea and Choreiform Affections.* By William Osler, M.D., F.R.C.P. (Lond.) etc. 8vo, pp. x, 125. Philadelphia: P. Blakiston, Son & Co. 1894.

A portion of this book has already been published in the lectures on chorea which appeared in the *Medical News* in 1887, and the statistics are based upon 554 cases in the records of the Philadelphia Infirmary for Diseases of the Nervous System. There is also a fairly good summary of the recent literature of the subject. The study of the subsequent condition of the heart in choreic patients, published by the author in 1887, has been continued, confirming the previous results. In 51¾ per cent. of the cases examined two or more years subsequent to the attack there were signs of organic heart lesion. In addition to the chapters on chorea the book contains a chapter on the habit spasms and tics, and one on Huntington's chorea, and a table of recent autopsies, seventy-three in number, which have been published since 1881, few of which seem to refer to the condition of the nervous system.

With the exception of the study of the heart the book contains little that is new. It is a useful compilation, such as might be made by almost any one having access to a good medical library and the records of a large clinic, but considering the author's reputation, such a production is a distinct disappointment. It is hastily compiled, and often we miss the conclusions which we might expect.

## THE SEMI-CENTENNIAL OF ANESTHESIA.

An extremely interesting anniversary has quite recently been celebrated in Philadelphia, and an account is given in the *International Dental Journal* for January.

December 11, 1844, was the day upon which Dr. Horace Wells, of Hartford, took nitrous oxide, and while under its influence submitted to the extraction of a wisdom-tooth for the purpose of testing the power of nitrous oxide to annihilate pain. On December 11, 1895, there assembled at Philadelphia a number of dentists and others to celebrate the fiftieth anniversary of that event. This action of Dr. Wells was brought about by his observation of the effects of laughing-gas as administered by Mr. S. Q. Colton, during popular lectures on chemistry. Wells took it himself, and was present while a Mr. Cooley bruised his knees in a way to attract the attention of the audience while he himself was unconscious of the bruise.

The anniversary was celebrated by addresses, a dinner and after-dinner speeches, which certainly did honor to the occasion. Not the least interesting individual present was the Mr. Colton, whose chemical lectures, with their exhibition of laughing-gas, were the starting-point in anesthesia evolution. Dr. Fillebrown, of Boston, spoke of the historic side of the discovery, and to his address we are specially indebted. Such great discoveries seldom leap unheralded upon the world. Anesthesia was said to be accomplished by the ancients, and the drugs first used in the modern history of anesthesia were known long before their practical application. In 1800 Sir Humphrey Davy made his remarkable statement, that "As nitrous oxide gas appears capable of destroying physical pain, it may probably be used to advantage during surgical operations in which no great effusion of blood takes place." One of the very interesting points in Dr. Fillebrown's address is the introduction of a letter from Oliver Wendell Holmes to Dr. Morton, in which he proposes the use of the words "anesthesia" and "anesthetic" as

the necessary noun and adjective to describe the new conditions.

The celebration was intended only to pay to Dr. Wells the tribute for the first application of an anesthetic agent. There was no desire apparent to rob others of the credit of their labors, without which anesthesia might still be awaiting its development; but all will be interested in Dr. Fillebrown's distribution of the honors among those connected with the early days of its history. Reduced to its baldest statement that distribution is as follows:

Dr. Wells observed the effect of the gas, and said, "I believe a man may, by taking that gas, have a tooth extracted or a limb amputated and not feel any pain." Dr. Wells further determined to try it on his own person. C. Q. Colton administered the gas to Dr. Wells for this first operation, and Dr. Riggs extracted one of Dr. Wells's molar teeth. Dr. E. E. Marcy suggested to Dr. Wells the use of ether instead of gas, and verified its action. Dr. Morton made the first public application of ether for surgical anesthesia. Dr. Jackson claimed to have suggested all that Morton knew. Dr. Simpson made himself famous by the popularization of the anesthetic power of chloroform. Dr. Holmes suggested for this condition of insensibility the name which has become universal. Dr. C. W. Long, of Georgia, used ether for anesthesia three times during 1842–3, but his connection with the subject was not mentioned until many years after the fact. Dr. Henry J. Bigelow's connection with the ether discovery was "important, perhaps vital, to the success of anesthesia at that time. . . . He practically supervised etherization during the first year of its use; he announced to the world the discovery of ether in a paper read at the Academy of Medicine November 3, 1846."

It is difficult at the present time to realize the opposition that was felt to the use of any agent intended to interfere with the "natural and physiological forces that the Divinity has ordained us to enjoy or suffer." It is scarcely credible that a clergyman should write that anesthesia is "a decoy of Satan, apparently offering itself to bless women; but in the end it will harden society and rob God of the deep, earnest cries, which arise in time of trouble for help."

The meeting was rightly felt to be not merely interesting but important, in its tribute to a man upon whose memory there remains no blot or stain; against whom "no charge of selfishness, dishonesty, deceit or unfairness was ever made." It was organized as a national tribute to the memory of Wells; the meeting at Hartford, December 10th, to which allusion was made in the JOURNAL, (December 13th, p. 596), and that in Boston, December 26th (JOURNAL, January 3d, p. 19), having a more local character.

AN ELABORATE TEMPERATURE CHART. — An elaborate chart for three-hourly temperature record, with space for pulse, respiration, record of bowels, urine, food, baths, etc., has been prepared by Dr. D. T. Lainé, M.P., and published by W. B. Saunders & Co., 925 Walnut Street, Philadelphia.

## ANIMAL EXTRACTS.

THE use of thyreoid extract in myxedema was based upon deductions drawn from careful scientific experimentation, and the benefits obtained from such use conclusively proved the correctness of these deductions. In consequence of the great success obtained in myxedema by the use of the thyreoid gland and its extracts, extracts have been made from many other organs, which have been used in various diseases quite empirically, and without any rational support from experiments. Several of them have even a factitious importance by the endorsement of certain well-known men. An interesting discussion in Germany[1] gives us valuable information as to the value of these extracts. Fürbringer states that the hypothesis in regard to certain glands is that they supply certain antitoxins to the blood, which render certain poisonous substances in it harmless, and prevent auto-intoxication; and that, when these glands are diseased, some form of intoxication follows. In regard to Brown-Séquard's testicular juice, Fürbringer, as the result of his own experiments, found neither a rejuvenating or an invigorating influence, which Brown-Séquard has tried to explain in other cases by the antipathy of the experimenters. Brown-Séquard claimed remarkable results in the treatment of tabes, epilepsy, neurasthenia, and even phthisis, but Massalango found as much benefit from injections of water in impotence, and Féré found the juice useless in epilepsy. Poehl has substituted spermine, which he claimed was a normal constituent of the blood, and was necessary where the oxydizing power of the blood was diminished. Little benefit has yet been shown from this; Posner and Eulenburg speak very guardedly of its action in tabes, and Fürbringer is still experimenting on it; but has seen little benefit from it. The treatment of myxedema by thyreoid preparations rests on a scientific, rational basis, and, like most observers, Fürbringer had found it beneficial. The treatment of diabetes by pancreas juice rests as yet on little experimental evidence, and in some cases of diabetes the pancreas is healthy; in two cases he obtained no benefit. Babes found that in neurasthenics treated for rabies by Pasteur's method the neurasthenic symptoms also disappeared, which he attributed to the injection of nerve matter. Cardine was claimed to show remarkable results in the treatment of heart disease, nephrine in renal disease, and hepatine and musculine have also been introduced. The value of all of these was still undetermined, and the clinical judgment very difficult, owing to the possibility of suggestion.

Leyden had tried pancreas in various forms in the treatment of diabetes without producing the slightest diminution in the amount of sugar.

Goldscheider had studied the effect of the animal extracts for a year and a half in Leyden's clinique. The changes produced by removal of the thyreoid or the testicles indicate that the glandular secretions are

[1] Verein für Innere Medicin. Therapeutische Monatshefte., April, 1894.

of great significance, and they furnish a scientific nucleus for their use, although their use is not free from danger. He had treated six cases of diabetes with pancreas juice without any benefit, and a case of exophthalmic goitre with thyreoid extract without any effect, good or bad. Pernicious anemia had been treated by preparations from the spleen and bone-marrow without benefit. Nerve matter was not thought worthy of serious discussion; spermine had not been tried. Spleen and bone-marrow were used with apparent benefit for a time in leukemia, but the patient soon died. Goldscheider considers the animal extract treatment dangerous for medicine. The laboratories should first isolate active principles, which can then be employed clinically.

Posner had tried spermine in neurasthenia and loss of sexual power, but without any benefit. Senator had tried pancreas juice in diabetes with no results. Spermine has given very good subjective results in tabes, but injections of normal salt solution did the same.

Except in the case of thyreoid extract the results from the use of all the other animal extracts seem almost wholly negative. The glandular secretions may furnish some substance necessary to the animal economy under normal conditions, as has been demonstrated in the case of the thyreoid; and, in disease, when this substance is no longer supplied, the glandular extracts may make up for the deficiency. For most of the glands, however, this is a mere hypothesis, and we need more experimental evidence before employing these extracts, of whose composition and action we know nothing, in the treatment of disease. Preparations from non-glandular tissues, the brain, the cord, the heart, and the muscles, are different. There is no evidence that they furnish any necessary substance to the economy, and the use of them in therapeutics has as yet not even a rational hypothesis to support it.

## RELAPSE AND IMMUNITY AFTER DIPHTHERIA ANTITOXIN.

WOLFF-LEWIN reports[1] a case of diphtheria in which a typical recovery under antitoxin treatment was followed in two days by the urticaria-like eruption, swelling of the joints, fever, etc., sometimes noted. Recovery from this attack took place in six days, and was followed two days later by a slight recurrence of the diphtheritic membrane on the left tonsil, attended by fever. Further continuance of the antitoxin treatment was thought unwise by the physician and the family of the patient. The recurrence ran a mild course and the patient fully recovered. Another very important point about this case is that the attack took place five weeks after an injection of Behring's antitoxin had been given with the object of conferring immunity. As the child was exceptionally exposed, a brother being ill with diphtheria in the same house, two doses of Behring's serum No. 1 (60 units) were given, a single dose being considered by Behring sufficient to produce immunity. As the immunity in this case lasted only five weeks, it would point at least to the conclusion that a double immunizing dose does not ensure a doubly long period of immunity.

The fact that Behring himself has recently increased the immunizing dose of antitoxin, and shortened the estimated period of immunity, shows that our knowledge of immunity in diphtheria is still very rudimentary. If the period of immunity depends upon the strength of the injection, it will certainly vary, for it seems hardly possible that even with the greatest care, an antitoxin serum of absolutely constant strength can be produced. The normal unit of strength is calculated on the basis of the amount required to protect a guinea-pig against a dose of toxin which proves fatal in other guinea-pigs. We have here a large element for variation in the varying resistance to the toxins of the animals employed, which can hardly be supposed to be constant. Other examples of an almost unavoidable uncertainty as to the strength of the toxins employed and antitoxins produced might be multiplied.

Practically there has been found to be a variation in the strength of the antitoxin produced by the British Institute of Preventive Medicine. Drs. Washburn, Goodall and Card, in the series of cases noted in our last issue, found that, immediately on beginning treatment with a new consignment of serum, a more rapid effect was noted, and a smaller dose was required to produce a given result. On investigation it was found that this consignment was the first product from a fresh horse not previously employed. Roux has noted marked variation in the strength of the serum produced at the Pasteur Institute, and has in one case been obliged to administer doses amounting to a total of nearly seven ounces.

It would seem, in the light of these experiences, that there might be some slight variation in the "*antitoxin-normal-einheiten*" produced under Behring's own direction.

Whether or not the period of immunity depends upon the strength of the injections, it will probably vary with unknown peculiarities of the patient, and be a very variable quantity, capable of approximation only within wide limits.

## HYPNOTISM AND MURDER.

NOT long ago a Kansas farm-hand named Macdonald murdered Thomas Pelten. When brought to trial Macdonald urged in his defence that he had been hypnotized by Pelten's enemy, Gray, and compelled to commit the deed by hypnotic suggestion. The jury therefore acquitted Macdonald and adjudged Gray guilty of murder in the first degree. Their verdict has been set aside by the Supreme Court and a new trial granted. Macdonald, the actual murderer, of

[1] Deutsch. Med. Wochenschrift, 1894, No. 52.

course goes free, and Gray can hardly be convicted on a new trial.

Granted that these statements, for which we rely upon the reports in the daily press, are accurate, the question which is thus brought forward is a serious one, and it is obvious that, if such a verdict were to stand, Kansas law would be far more fatal to society than Kansas political economy. We may accept the modern theories as to the criminal, and admit that he is the inevitable product of bad heredity, evil environment, and degeneration; we may often question how far he is responsible for his criminality, but when it comes to the practical point society decides that, for its own protection, the criminal must suffer for his acts in person, and not through his parents or his evil neighbors. If the criminal himself is to escape, and if the punishment is to fall on those who have influenced him to evil, the results will be disastrous. All our criminals will at once claim to be honest but misguided folk, and some of our best citizens may be accused of instigating others to crime. This theory had a practical application here in Massachusetts two centuries ago. Several mischievous young persons escaped a well-deserved whipping and a number of harmless old women were hanged for having bewitched them, and thus compelled them to do many ill deeds against their will.

Not even the marvellous properties attributed to hypnotism can induce us to go back into the dark ages and rake up once again the belief in witchcraft. Unfortunately the study of hypnotism seems peculiarly adapted to develop the credulity of the student, and the literature of the subject to-day contains a vast amount of matter that cannot stand scientific criticism. At the trial of Gabrielle Bompard in Paris, Bernheim and other leaders of the so-called Nancy school, urged the same defence as in Macdonald's case, but the verdict was not in accordance with their views. In spite of the make-believe "laboratory" crimes committed under hypnotic influence, the weight of evidence is in favor of the belief that an honest man cannot be made to commit crime under such influence. Moreover, even Bernheim admits that no one can be hypnotized against his will. The alleged tool of the hypnotizer has therefore voluntarily made himself the agent, and has yielded to suggestion as another might yield to alcohol. If we accept the extreme views as to suggestion, the paid murderer has simply yielded to the suggestion of gold. The hypnotized murderer might have resisted at first, but, not having done so, he ought inevitably to suffer the consequences of his acts. If it can also be proved that the hypnotizer suggested the crime, and planned its details, he becomes an accessory before the fact and is likewise amenable to the law. The Kansas verdict is not in accordance with scientific facts or sound jurisprudence, yet its contagion has already spread into another State, and, in view of the enormous amount of credulity in the community, we fear that other criminals may also escape well-merited punishment.

## MEDICAL NOTES.

MCGILL UNIVERSITY SEEKS PROF. WM. OSLER. — Prof. William Osler of the Johns Hopkins University, has been offered the position of president of McGill University, Montreal.

"PASTEUR STREET." — The Municipal Council of Paris has decided to change the name of the *Rue d' Ulm* to Rue Pasteur, in honor of the distinguished scientist.

A GOOD EXAMPLE.— The City of Sydney, Australia, has imposed a fine of one pound sterling upon any person convicted of spitting upon the floor of public buildings or upon the street.

THE SIXTIETH BIRTHDAY OF PROFESSOR SENATOR.— The sixth of last December was the sixtieth birthday of Professor Senator, the distinguished Berlin clinician. In honor of the occasion he was presented by his assistants in the clinic and polyclinic with photographs of all his former and present assistants, as well as of the Augusta Hospital, the Charité and the Polyclinic.

THE INDIAN MEDICAL CONGRESS.— The first Indian Medical Congress, was opened in Calcutta on Christmas Eve by the Viceroy of India in the presence of many European and native officials. Surgeon-Colonel R. Harvey, M.D., F.R.C.P., D.S.O., delivered an opening address, in which he eloquently expatiated on the progress in medical and sanitary science made in India. The papers announced to be read before the Congress number 203, and embrace a wide range in medicine, surgery, both general and special, and sanitation.

RECOVERY AFTER EXTIRPATION OF A CYST OF THE PANCREAS. — P. Zweifel (*Cent. für Gyn.*, 1894, No. 27) reports in full the history of a case of cyst of the pancreas for which he had operated, removing the entire cyst with recovery of the patient. Although the hemorrhage is very great is these cases, he was enabled to keep it in check by seizing hold of the tissues with forceps, ligating and cutting between the ligatures. He considers extirpation far superior to drainage, as the convalescence is so much more rapid and satisfactory. The patient four months afterward was in perfect health, and the urine which had been highly diabetic did not show a trace of sugar.

PENNSYLVANIA STATE MEDICAL SOCIETY. — The members of the Medical Society of the State of Pennsylvania who wish to read papers at the meeting to be held at Chambersburg, May 21–24, 1895, will please send their names and the titles of the papers they wish to read to the Chairman of the Committee on Scientific Business, Dr. Charles W. Dulles, 4101 Walnut Street, West Philadelphia. The Committee desires papers to be *absolutely* no longer than ten minutes. At the last meeting a large number of interesting papers were not read because those preceding them were too long, and it is to be hoped that those who prepare papers for the coming meeting will

condense them as much as possible. The laws of the society permit each writer to occupy twenty minutes, but it will be of advantage if the members of the society do not avail themselves of all their privilege.

Proposed Testimonial to Sir Henry Acland. — A movement is on foot to secure a memorial of the work of Sir Henry Acland, on his retirement from the Regius Chair of Medicine in Oxford, which is to take the form of a provision for the increased usefulness of the Sarah Acland home for nurses. £10,000 is thought necessary for the acquisition of a better site and better premises and £1,055 have already been subscribed. Among the subscribers are the Prince of Wales, the Right Hon. W. E. Gladstone, the Earl of Roseberry, etc. Subscriptions will be received by Messrs. Parsons & Co., Old Bank, Oxford; London & County Bank, Oxford; Messrs. W. Wootten & Co., Oxford; Messrs. Gillett & Co., Oxford.

Memorial to the Late Dr. Sturges. — A numerously attended meeting was held on Wednesday, December 19th, at Westminster Hospital, to raise some memorial to the late Dr. Octavius Sturges, the senior physician. The chair was occupied by Mr. George Cowell, F.R.C.S. Eng., senior surgeon to the hospital. The following resolution was carried unanimously, "That this meeting cordially approves of the proposal to establish a memorial to Dr. Sturges, and pledges those present to make every exertion to promote this object." The second resolution, also carried unanimously, was as follows, namely: "That the memorial be a prize, exhibition, or scholarship in connection with the Westminster Hospital Medical School, with which Dr. Sturges was so long associated; a portion of the money raised being set aside for the purchase of four permanent photographic portraits of Dr. Sturges, and to cover the cost of a small photograph to be issued with the forthcoming volume of the hospital reports."

Antitoxin in Denver. — According to the Denver papers, to Denver belongs the distinction of being the first place west of the Missouri River to test the merits of the antitoxin in a severe case of diphtheria. Antitoxin of Berlin manufacture has been tried upon two cases, one mild and one severe, both of which recovered. At the instance of the Arapahoe County Medical Association, enough antitoxin has been imported and brought to Denver to treat seven cases, the expense being defrayed in part by contributions from the members of the association.

Serum Therapeutics in a Vienna Hospital. — At the last meeting of the Vienna Society of Physicians, Professor Widerhofer made a report on the results obtained by the serum therapeutics at the St. Ann Hospital for Sick Children. The mortality from diphtheria at this hospital from 1862 till 1894 varied between 32.3 and 71.9 per cent. The incidence and mortality from diphtheria were generally highest in the months of October, November and December. In October to December, 1891, the mortality was 34.2 per cent., and in the corresponding periods of 1892, 39.0 per cent.; in 1893 it was 44.0 per cent.; and in 1894 only 24.0 per cent. One hundred cases of diphtheria were subjected to the treatment from October to December, 1894. Among them 8 were one year of age, 7 two years of age, 17 three years of age, and the others were between four and six years of age. The patients were kept in hospital as long as Löffler's bacillus could be found. All diphtheritic patients admitted to hospital were injected, even if the admission took place later than on the fourth day of the illness. Patients who died from lobular pneumonia two weeks after they had left the hospital were also grouped with the statistical tables. Of these 100 cases 23 died, 74 recovered, and 3 remained under treatment. On the day of the meeting one of the latter who had had laryngeal diphtheria died from a recent attack of diphtheria. The mortality was, therefore, 24 per cent., while it had been 52.6 per cent. during the nine preceding months of the year.

A Triumph of Orificial Surgery. — An orificial surgeon reports in a recent number of a medical journal a case of "phthisis" cured by the operation for laceration of the cervix. The patient had a severe and long-continued cough and hectic fever, and what the surgeon calls an "interstitial inflammation of the lungs," with infiltration and obstruction of the air cells. "On the day of the operation the temperature reached 97.6°, and never rose above 99° afterwards." Some light is thrown upon the nature of the case by the surgeon's stating that it was a case of phthisis of neurotic origin, and that such cases are often successfully treated by "removing the distal point of pathology." Other successful results of "orificial surgery" are a case in which chronic eczema of the hands was cured by stretching the rectum, and another case of the same disease cured by loosening the "hood" of the clitoris and "clipping of irritated points at the various outlets of the body." Of course all the resources of therapeutic art had been exhausted upon these cases before they came under the care of the "orificial surgeon." A more transparent form of quackery than some of this orificial surgery can hardly be imagined. The author of the article referred to above states that in his observation "many cases of insanity are made worse by the operative procedure, but the secondary effect is most satisfactory." In his opinion "a conservative orificial surgeon should be connected with each of our State hospitals for the insane." This last idea seems an excellent one, if he be connected in the proper capacity, that is, as a patient rather than as a surgeon.

## NEW YORK.

Influenza in New York. — Influenza seems to have become epidemic in the city, but thus far the mortality has not been as great as in some former outbreaks. During the week ending January 5th seven deaths were reported as due to this cause and in the week ending January 12th, twenty-eight. During

the latter week the weather was exceptionally bad, and the total number of deaths in the city was over one thousand.

THE DEATH-RATE FOR 1894. — The death-rate for the year 1894 has been officially announced as 21.03 per thousand of the estimated population, and it is the lowest reported for many years. In the city of Brooklyn 21,183 deaths were reported during the year.

DEATH OF DR. HALLAM. — Dr. Albert C. Hallam, a prominent physician of Brooklyn, died at his residence in that city, January 9th. He was born in Watertown, Conn., in 1845, and studied medicine at the Yale Medical School, from which he was graduated in 1866. All his professional life was passed in Brooklyn.

THE PRODUCTION OF ANTITOXIN SERUM. — A delegation from Philadelphia, consisting of Dr. Beiller, Commissioner of Public Safety, Dr. Shakespeare, of the State Bacteriological Department, and Drs. Ford and Heiser, members of the Philadelphia Board of Health, on January 12th visited the laboratories and stables of the New York Board of Health for the purpose of inspecting the preparation of antitoxin. The visitors were escorted by Drs. Biggs, Parks and Beebe, who showed them the various processes. The Board of Health has appointed as inspectors to furnish antitoxin to the medical profession of the city, Drs. Densell, of the Bureau of Contagious Diseases, and Dr. Huddleston, of the Bacteriological Department.

BEQUESTS TO THE COLLEGE OF PHYSICIANS AND SURGEONS. — At a meeting of the Trustees of Columbia College held January 7th, President Low announced that the College of Physicians and Surgeons had received two very large gifts, one of $350,000 from Cornelius, William, Frederick and George Vanderbilt, who each contributed $87,500, and one of $200,000 from William D. Sloane. The Messrs. Vanderbilt specify that their gift is to be used in the enlargement of the main college building and also of the Vanderbilt Clinic, and the Sloane gift is for the purpose of erecting a new maternity hospital to be connected with the present one and form a part of it. Mrs. Sloane, who is a sister of the Vanderbilts, agrees to furnish funds for the maintenance of the new hospital after it has been built and equipped by her husband. This last gift of Mr. and Mrs. Sloane will make their total donations to the college over $1,000,000, and the same is true of the Vanderbilt contributions.

DEATH OF DRS. FITZGERALD AND ROOF. — Two well-known physicians died suddenly of cardiac disease on January 7th, and January 9th, Drs. Joseph S. Fitzgerald and Stephen W. Roof. Dr. Fitzgerald was found dead on the morning of the 8th at the Dispensary on West 139th Street, where he had attended his clinic the evening before. He was 49 years of age and a graduate of the Georgetown Medical College in the year 1870. Dr. Roof died at the armory of the Ninth Regiment, National Guard, where he had gone for bicycle exercise. He was 51 years of age, and was born at Somerstown, Westchester County, New York. He was graduated at the College of Physicians and Surgeons in 1864. He was for 15 years surgeon of the Ninth Regiment, and at the time of his death was surgeon of the Ninth Regiment Veteran Association.

## Miscellany.

### THERAPEUTIC NOTES.

A NEW ANTIPYRETIC. — Tussol is the name given to a compound of amygdalic acid and antipyrine. Dr. Rehn, of Frankfort-on-the-Main, has used the drug recently in quite a number of cases of whooping-cough in children. He has found it useful in reducing the frequency of the paroxysms and mitigating their intensity, that its action is different from that of simple antipyrine, and that no untoward effects have been observed from its use. It is soluble in water, and as a corrigent raspberry syrup is better than milk. The minimum doses for children are as follows: Under one year of age, from three-quarters of a grain to a grain and a half, two or three times a day; from one to two years, a grain and a half, three times a day; from two to four years, from three grains and three-quarters to six grains, three or four times a day; for older children, seven grains and a half, four times a day or oftener.

CACTUS GRANDIFLORUS. — Mr. Gordon Sharp,[1] after a careful study extending over two years, of the literature, pharmacology and therapeutics of *Cactus grandiflorus*, a claimant for favor with digitalis, concludes as follows: "The literature of *Cactus grandiflorus* is comparatively extensive, but vague, too many properties being ascribed to the drug, and upon too slender evidence; there being no authoritative evidence of a pharmacological or carefully carried out therapeutical kind. The chemistry is as yet unknown, authorities on this subject not even mentioning the presence of a glucoside or alkaloid; and, so far as we can make out after extensive trials, we have been unable to obtain either of those bodies. The most important agents we find to be a series of resins. The pharmacology is necessarily indefinite, one having to work with rather insoluble resins. These contract the blood-vessels of a frog, but this is not of the nature of a digitalis contraction, but depends, I believe, on simple acidity. On the heart of the frog the resins have little or no effect, comparisons being made with digitalis in the same animal. The drug itself would appear to be pharmacologically inert, and there is no proof that it shortens diastole, nor in fact that it has any special action on the heart muscle at all. The therapeutics of the subject I think are clear enough. *Cactus grandiflorus* cannot be included in our list of cardiac drugs. It is not even a simple stomachic tonic, and at most all one can say is that it has some small diuretic action." The few reported instances in which it appears of any service were cases in which it was combined with some effective drug like nux vomica and consequently not of any test value.

## Correspondence.

### PHOTO-MICROGRAPH *VERSUS* MICRO-PHOTOGRAPH.

SYRACUSE, N. Y., January 12, 1895.

MR. EDITOR: — From time to time it seems to be necessary to call attention to the confusion in the use of the words herein considered. In the *Boston Medical and Surgical Journal* of January 3, 1895, in table of contents of the New York Neurological Society, and in report at page 14, the word "micro-photograph" is not correctly used. Micro-photographs are curios mounted on microscopic slips or in miniature opera-glasses, handles of pen-holders, etc. In a paper read by me before the American Society of Microscopists in 1886, is the following account and definition:

The confusion of the terms "photo-micrograph" and "micro-photograph" has led the writer to try to discover the paternity and original meaning of the more important word, photo-micrograph.

During the past eighteen months, through the kind interest of Dr. R. L. Maddox himself, and through him of the editors of the *British Journal of Photography*, the looked-for paternity has been discovered. Traced to Mr. George Shadbolt, he has acknowledged the child, writing: "I believe I am responsible for drawing attention to the necessity of a distinction between a photographic picture of an enlarged object and the minute photographic picture of a large object, the former being correctly described as a 'photo-micrograph' and the latter as a 'micro-photograph,' in accordance with the meaning of the original Greek derivatives. This will have been in an early number of the *British Journal of Photography*, probably while it was still called '*The Liverpool Journal of Photography.*'"

The exact date of the birth of the word is still somewhat doubtful, but Dr. Maddox writes: "I think we may safely put it at 1859 or 1860, although we cannot put our finger on the page even after much research."

The two acknowledged leaders in photo-micrographic literature in the two great English-speaking countries, Drs. Maddox and Woodward, throughout their writings have used the words in question with the clearly-defined Shadbolt distinction; and the writer trusts, with this historical note recorded in our Proceedings, the American Society of Microscopists, as a body and as individuals, will insist upon the correct usage of these terms.

A photo-micrograph is a macroscopic photograph of a microscopic object; a micro-photograph is a microscopic photograph of a macroscopic object.

Yours truly,
A. C. MERCER, M.D.

### "SCARLET FEVER, WITH ESPECIAL REFERENCE TO CONTAGION AND PROPHYLAXIS."

WEST NEWTON, MASS., January 15, 1895.

MR. EDITOR: — In the issue of the JOURNAL for January 10, 1895, Dr. W. C. Holyoke in an article on "Some Cases of Scarlet Fever with Especial Reference to Contagion and Prophylaxis," refers to an outbreak of scarlet fever in the Rutland Street Home during January and May, 1894.

The doctor attributes the outbreak to some toys which were received at the Home on January 2, 1894, from Newton Centre, where, he says, newspaper reports indicated that scarlet fever was prevalent at the time the toys were collected.

The records of the Board of Health of Newton show that there was no scarlet fever in Newton Centre between July 20, 1893, and January 15, 1894, so that it seems impossible that these toys should have been the cause of the outbreak referred to.

Very respectfully,
FRANCIS GEO. CURTIS, M.D.,
*Chairman Newton Board of Health.*

### METEOROLOGICAL RECORD,

**For the week ending January 5th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—**

| Date. | Barometer | Thermometer. | | | Relative humidity. | | | Direction of wind. | | Velocity of wind. | | Weather. | | Rainfall in inches. |

| Newburyport | 14,073 | 4 | 0 | — | — | — | — | — |
| Amesbury | 10,920 | — | — | — | — | — | — | — |

Deaths reported 2,845: under five years of age 980; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 394, acute lung diseases 541, consumption 294, diphtheria and croup 218, scarlet fever 43, typhoid fever 33, diarrheal diseases 20, measles 15, whooping-cough 10, cerebro-spinal meningitis 9, erysipelas 5, small-pox 4.

From diarrheal diseases New York 6, Philadelphia and Cleveland 3 each, Fall River and Lowell 2 each, Brooklyn, Washington, Providence and Worcester 1 each. From measles New York 11, Brooklyn 2, Providence and Springfield 1 each. From whooping-cough New York and Worcester 3 each, Brooklyn 2, Philadelphia and Lawrence 1 each. From cerebro-spinal meningitis New York 4, Lynn 2, Washington, Providence and North Adams 1 each. From erysipelas New York and Brooklyn 2 each, Worcester 1. From small-pox Philadelphia 3, Brooklyn 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,458,442, for the week ending December 29th, the death-rate was 18.0 Deaths reported 3,615; acute diseases of the respiratory organs (London) 332, measles 153, diphtheria 64, fever 56, whooping-cough 51, scarlet fever 34, small-pox (London, Birmingham, Liverpool and Hull 1 each) 4.

The death-rate ranged from 6.5 in Croydon to 26.2 in Preston; Birmingham 17.5, Bolton 18.1, Brighton 23.3, Hull 18.9, Leeds 21.3, Leicester 13.2, Liverpool 21.8, London 17.2, Manchester 18.5, Newcastle-on-Tyne 18.3, Nottingham 16.8, Sheffield 19.3, Swansea 15.3, West Ham 13 6.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 5, 1895, TO JANUARY 11, 1895.

The leave of absence for seven days granted CAPTAIN REUBEN L. ROBERTSON, assistant surgeon, is extended twenty-one days.

Ordinary leave of absence for one month and fourteen days, in addition to the extension of leave of absence on surgeon's certificate of disability granted him, is granted CAPTAIN ADRIAN S. POLHEMUS, assistant surgeon.

The leave of absence granted FIRST-LIEUT. CHARLES LYNCH, assistant surgeon, is extended one month.

FIRST-LIEUT. GEORGE DESHON, assistant surgeon, will proceed from Fort Logan, Colorado, to Fort Douglas, Utah, and report for temporary duty.

Leave of absence for three months on surgeon's certificate of disability, is granted CAPTAIN WM. C. SHANNON, assistant surgeon, U. S. A.

Leave of absence for one month is granted FIRST-LIEUT. HENRY C. FISHER, assistant surgeon.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 12, 1895.

AMMEN FARENHOLT, assistant surgeon, detached from the U. S. Receiving-ship "Vermont" and to Naval Hospital, Norfolk, Va.

C. P. KINDLEBERGER, assistant surgeon, detached from Naval Laboratory and Department of Instruction and to the U. S. Receiving-ship "Vermont."

GEO. H. COOKE, medical inspector, in addition to present duties will attend officers on duty at League Island Navy Yard, but residing outside of the yard.

## HARVARD MEDICAL SCHOOL.

### EVENING LECTURES.

The next lecture will be given on Thursday evening, January 24th, at 8 o'clock, by Prof. H. C. Ernst. Subject, "Immunity." Physicians are cordially invited.

## SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. – A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday evening, January 21st, at eight o'clock.

Drs. J. W. Elliot, W. F. Whitney and E. G. Cutler will read on "Pancreatic Hemorrhage."

JAMES G. MUMFORD, M.D., *Secretary*.

## APPOINTMENTS.

At the January meeting of the Board of Managers of the Boston Dispensary the following appointments were made:

DRS. MALCOLM STORER and BENJAMIN TENNEY to the Medical staff at the Central Office; DR. WM. E. CHENERY to the staff of the throat department; DR. EDWARD H. NICHOLS to the orthopedic department, and DRS. E. CHANNING STOWELL and WM. L. EDWARDS, district physicians.

## RESIGNATION.

DR. R. M. HODGES has resigned his position on the Massachusetts Board of Lunacy and Charity.

## RECENT DEATHS.

MYRON LESLIE BAXTER, M.D., of Derby Line, Vt., is dead at the age of fifty-six. He was a graduate of the University of Vermont. He served as surgeon during the Rebellion and was a brother of the late surgeon-general, J. H. Baxter, U. S. A.

DR. HENRY H. CAMPBELL, of Waterville, Me., died recently, aged seventy-four. He was born in Farmington and was educated at Bloomfield Academy and Dartmouth and Jefferson Medical Schools. He practised in Waterville for forty years.

## BOOKS AND PAMPHLETS RECEIVED.

Sixth Annual Report of the Trustees of Morton Hospital for the year ending February 28, 1894.

Ligature of the Spermatic Cord in the Treatment of Hypertrophy of the Prostate Gland. By J. Ewing Mears, M.D., Philadelphia. Reprint. 1894.

Report of the Trustees of the Rhode Island Hospital, Presented to the Corporation at its Thirteenth Annual Meeting, November 8, 1893. Providence. 1893.

The Proceedings of the Fourth Annual Meeting of the Association of Military Surgeons of the United States held at Washington, D. C., May 1-3, 1894.

Atlas of Clinical Medicine. By Byrom Bramwell, M.D., F.R.C.P., Edin., F.R.S., Edin., Assistant Physician to the Edinburgh Royal Infirmary, etc. Volume III. Part 1. Edinburgh. 1894.

Inoculation for Diphtheria and Croup. [Report on the Treatment of Diphtheria and Croup by Means of Hypodermic Injections of Diphtheria Serum. By C. W. Chandler, United States Consul at Havre, France.]

Diagnosis, Differential Diagnosis and Treatment of Diseases of the Eye. By A. E. Adams, M.D, Instructor in Diseases of the Eye in the Post-Graduate Medical College, etc. New York: G. P. Putnam's Sons. 1894.

The Soldier's First Aid Handbook, Comprising a Series of Lectures to Members of the Hospital Corps and Company Bearers. By William D. Dietz, Captain and Assistant Surgeon, U. S. A. New York: John Wiley & Sons. 1891.

Notes on Military Hygiene, for Officers of the Line: a Syllabus of Lectures at the U. S. Infantry and Cavalry School. By Alfred A. Woodhull, Major, Medical Department, Brevet Lieutenant-Colonel, U. S. A. New York: John Wiley & Sons. 1893.

On Chorea and Choreiform Affections. By William Osler, M.D., Fellow of the Royal College of Physicians, London; President of the Association of American Physicians; Professor of Medicine, Johns Hopkins University. Philadelphia: P. Blakiston, Son & Co. 1894.

Report on Typhoid Fever in the District of Columbia, submitted by the Medical Society of the District of Columbia to the Committee on the District of Columbia of the U. S. House of Representatives, June 14, 1894. Washington: Government Printing Office. 1894.

The History of Education in Connecticut. By Bernard C. Steiner, A.M. (Yale), Instructor in History, Johns Hopkins University; Librarian of the Enoch Pratt Free Library of Baltimore. Washington, D. C.: Bureau of Education, Circular of Information, No. 2. 1893.

Points in the Etiology and Clinical History of Erysipelas. The Complicating Conditions, Associated Diseases and Mortality-rate in Erysipelas. The Treatment of Erysipelas. Beriberi, with Report of Cases. By J. M. Anders, M.D., Ph.D., Philadelphia, Pa. Reprints. 1893-94.

A Dictionary of Medicine, Including General Pathology, General Therapeutics, Hygiene and the Diseases of Women and Children. Edited by Richard Quain, Bart., M.D., Lond., etc., and others. With an American appendix. New edition. Two volumes. New York: D. Appleton & Co. 1894.

Physiology for Beginners. By M. Foster, M.A., M.D., F.R.S., Professor of Physiology in the University of Cambridge, and Lewis E. Shore, M.A., M.D., Fellow of St. John's College, Cambridge, and Senior Demonstrator of Physiology in the University of Cambridge. New York and London: Macmillan & Co. 1894.

A Synopsis of the Practice of Medicine for Practitioners and Students. By William Blair Stewart, A.M., M.D., Lecturer on Therapeutics; late Instructor on Practice of Medicine in the Medico-Chirurgical College of Philadelphia; Demonstrator in the Philadelphia School of Anatomy, etc. New York: E. B. Treat. 1894.

The Physiology of the Carbohydrates; Their Application as Food and Relation to Diabetes. By F. W. Pavy, M.D., LL.D., F.R.S., Fellow of the Royal College of Physicians; Consulting Physician to and formerly Lecturer on Physiology and on the Practice of Medicine at Guy's Hospital. London: J. & A. Churchill. 1894.

The History of Education in Delaware. By Lyman P. Powell, A.B., Fellow in the Wharton School of Finance and Economy in the University of Pennsylvania, and Staff Lecturer on History to the American Society for the Extension of University Teaching. Washington, D. C.: Bureau of Education, Circular of Information, No. 3. 1893.

## A CONSIDERATION OF SOME OF THE INDICATIONS FOR OPERATION IN HEAD INJURIES.[1]

BY WILLIAM N. BULLARD, M.D.,
*Physician to Department of the Diseases of the Nervous System, Boston City Hospital.*

THE subject of the indications and contra-indications for operations in head injuries is so large that it will be possible to cover only a small portion of the ground this evening, and I shall therefore confine myself to presenting to you certain points which seem to me to have not yet been appreciated at their full value by the profession. For the purposes of this paper it will be necessary to limit ourselves to the consideration of some of the indications for *immediate* operation in cases of head injuries in *adults*. By immediate operations we understand such as are performed within at least twelve hours of the time of the injury. As a rule, the operations under consideration are to be performed within as short a time after the injury as possible.

The indications for later operations, that is, more than twelve hours after the injury, differ very considerably from those for immediate operations, and are, on the whole, much easier for determination. These we will not consider to-night.

The symptoms on which we rely in order to decide on the advisability of immediate operation in cases of severe head injury may be roughly divided into four groups: (1) extracranial or cranial local symptoms, (2) intracranial local symptoms, (3) extracranial general symptoms, (4) intracranial general symptoms.

(1) The direct local symptoms, those which are immediately due to the injury and are perceptible to the surgeon. Such are wounds, ecchymoses, evident fractures of the cranium and all other local and evident conditions due to direct injury in any part of the body, which have any bearing on the diagnosis or prognosis. These are *local extracranial* or *cranial* symptoms.

(2) The intracranial or indirect local symptoms. In this group I would include all localized symptoms which are to be referred to intracranial conditions. Such are the various forms of paralysis, partial or total, of local spasms and certain conditions of the pupils. Symptoms of this group point more or less distinctly to affections of special portions of the intracranial organs, and so far as they do so are *localizing*.

(3) The third group is a somewhat indefinite one. It includes such general symptoms and conditions as may exist after any injury without special relation to intracranial conditions. Under this heading I should place the general strength or weakness of the patient and the condition of the pulse. I have called the symptoms of this group the extracranial general symptoms.

(4) The intracranial general symptoms. This includes all general conditions presumably due to intracranial conditions. Such are the states of cerebral activity or of cerebral repose; consciousness, semi-consciousness, unconsciousness, coma and delirium. These may be reasonably referred to intracranial conditions caused by the injury and may be fairly considered as the *index* of these conditions.

[1] Read before the Surgical Section of the Suffolk District Medical Society, December 5, 1894.

The direct external symptoms are too well known to every surgeon to render their discussion valuable. The localizing symptoms, though often of great value in combination with other symptoms, in themselves rather determine *where* we shall operate than *when* we shall operate.

I propose this evening to pass over the symptoms which I have placed in the first three groups, and devote myself principally to the consideration of those general symptoms indicative of intracranial conditions which we have mentioned in the last group.

It is largely from the general mental condition of the patient, meaning by this term those states or conditions which we have before enumerated, consciousness or unconsciousness, delirium, quiet or irritation, that the indications or counter-indications for immediate operation in head injuries are in many cases to be drawn. We will now, therefore, consider the indications for and against immediate operation in cases of severe head injury in adults where the external signs and the localizing symptoms do not exist or do not afford sufficient indication.

The *primary* indication for immediate operation in severe head injuries is *increased intracranial pressure*. The question of operation in these cases depends on the degree of this pressure.

Whenever it has reached a certain point operation is imperative, unless otherwise contra-indicated. This point is the condition of deep stupor where the patient cannot be roused by supraorbital pressure. When, however, the unconsciousness is deep, but the patient can still be roused by passive movements or in other ways, the indication is less definite. Yet in all such cases, and they form a large proportion of those entering the large hospitals, we must be largely guided in our action by the depth of this unconsciousness.

Cases of this kind, as a rule, grow more unconscious during the first few hours, so that if we wait we may often be obliged to act rapidly later. On the other hand, the lighter cases of unconsciousness, which do not tend to become more unconscious, should not be operated upon at once. In any doubtful case the most careful watch should be kept for any increase in the degree of unconsciousness, and as soon as this has been thoroughly determined operation should be performed.

In all cases, whether only lightly or deeply unconscious, where there has been a rapid increase in the depth of unconsciousness, or where there is a distinct increase of paralysis of the extremities within the course of a few minutes or hours after the injury, operation should be performed. Gradual increase of paralysis and gradual increase of unconsciousness becoming apparent shortly after a head injury, suggest intracranial hemorrhage, usually middle meningeal, and demand immediate surgical interference in all persons under forty years of age. In persons much above this age, in cases where the external injury is slight or doubtful, the question of the presence of slow hemorrhage from some of the deep vessels of the cerebrum (ingravescent apoplexy) must be considered.

When together with unconsciousness there exists cerebral activity or irritation, as evidenced by delirium, it has usually seemed to me more advisable to wait and not operate at once, although some of these cases have fatal terminations. On the whole, I consider delirium as rather a sign for delay than for immediate action. Where delirium without unconsciousness exists, it con-

tra-indicates operation or indicates that we should not operate at once.

Localized cerebral irritation, as evidenced by clonic convulsions, either general or local, is not a common sign of head injury (surgical). In cases where there is no history, convulsions render it probable that the case is non-traumatic, or that some ordinarily non-traumatic condition has been set up by the trauma. These are the results of clinical experience.

It would seem scarcely needful to state that in each individual case we must consider the special symptoms and indications. In those cases in which there is no evidence of paralysis, and no pupillary symptoms exist, we rely on the general condition of the patient. The important signs are two: (1) the depth of unconsciousness, (2) the increase of unconsciousness.

(1) It is hard to define exactly the degree of unconsciousness at which — there being no special contra-indication — operation is absolutely demanded. In most of the more doubtful cases we have some secondary symptoms (fracture, paralysis, pupillary conditions) to guide us. Where these do not exist, we must rely to a certain extent on the general appearance of the patient, his pulse, apparent strength and respiration. If his strength is failing but he can still bear operation, operate at once. As a rule, we should advise operation in any case where the patient (adult) could not be roused by supraorbital pressure and where the pupils did not react to light.

(2) When the unconsciousness, light at first, rapidly becomes deeper, especially if this be accompanied by any commencement or increase of paralysis, we should at once suspect intracranial hemorrhage, usually middle meningeal.

Where an unconsciousness, deep from the beginning, becomes slowly and very gradually deeper, without an increase of paralysis of the face or limbs, we can only diagnosticate an increase of intracranial pressure, and cannot determine whether such increase be due to hemorrhage or not.

What now are the pathological conditions existing in these cases? I believe that wherever the conditions of lasting unconsciousness, stupor and coma exist, we have to deal with an increase of intracranial pressure. This conclusion is based on the results of many operations and observations.

The cause of this increase of intracranial pressure is not altogether plain. It is *not by any means*, as is sometimes supposed, *always* a pressure from intracranial hemorrhage. In fact, I am inclined to believe that pressure from this cause is much less frequent than is supposed. It takes a considerable quantity of blood to produce from outside the brain substance an active pressure on the brain, even when the pressure is produced rapidly.

In many cases, moreover, on operation we have no evidence suggestive of any severe hemorrhage, and yet the increased pressure is apparent. Again, this increased pressure in all probability occurs in the cases of so-called concussion, and in other mild cases where unconsciousness exists but where there can be no question of any profuse hemorrhage. What seems to occur is this: The brain in some way acts as a sponge, and swells and pushes so hard against the dura as to inhibit or diminish pulsation. If in these cases the dura is incised, the cerebral pulsation again becomes visible, and the relief to the patient is instantaneous and extraordinary.

And here let me state that after a tolerably large experience in these operations I have never seen a case in which the incision of the dura has caused the slightest injury to the patient, or has apparently caused any untoward symptoms whatever. The cause of this brain swelling I will not discuss to-night, because it is a difficult subject, not well understood, and, moreover, has immensely broad bearings in various directions. It occurs undoubtedly in certain cases of apoplexy and, in a chronic form, in many intracranial diseases. This or something analogous, the so-called acute edema of the brain, is the immediate cause of death in cases of acute alcoholism, of sunstroke and perhaps (in its chronic form) in uremia.

Let us now pass to certain surgical considerations in operations such as we are discussing. It is evident that unless the operation be of a suitable and efficient character, its value is likely to be much impaired and the result not conformable to our expectations. It is as important to know *how* to operate as it is *when* to operate or *where* to operate. It may seem a little presumptuous for one who is not a practical surgeon to attempt to speak on this subject, but I have for years followed these operations with care, and feel justified in laying down certain rules. These are:

(1) Be sure that the opening in the cranium is sufficiently large. In the early days of these operations, and to a certain degree even to the present time, there has been a tendency on the part of the surgeon in exploratory trephining or opening of the cranium to make his aperture too small.

This is a serious matter, both because it prevents the surgeon from seeing and from working inside the cranium at his ease, and still more because it prevents him from opening the dura sufficiently, and efficiently relieving the intradural pressure. I believe that in the ordinary case nothing smaller than a one-inch trephine should be used, and then the opening enlarged, with bone forceps, if possible. An opening, as a rule, to be efficient should be at least two inches by one. Of course it makes no difference how this opening is made providing that it is made as *quickly* as possible, with as little jar as may be to the patient and without laceration of the dura.

(2) The second point to be emphasized in these operations is always to open the dura where there is evidence of intradural pressure. There is no more danger in opening the dura under proper antiseptic or aseptic precautions than there is in opening any other serous cavity. The superstition that the dura was a structure which it was exceedingly dangerous to meddle with dies hard, and still lingers consciously or unconsciously in the minds of many surgeons and physicians. I can only repeat that having closely observed for a number of years a very considerable number of patients in whom the dura has been opened, either intentionally or otherwise, I cannot recall a single case *in an adult* where any essential harm was produced. In a very large proportion of cases there is neither any perceptible shock at the time, nor are any future harmful effects (of no matter how slight a character) perceptible.

(3) Remember that in these operations time is an important factor. Do what has to be done as rapidly as possible. In children many deaths are caused in these operations by loss of time. In adults the consequences are not, as a rule, so serious, nevertheless next to asepsis time is probably the most important

factor in the success of an exploratory cranial operation.

(4) In an exploratory operation, where it is not certain that a large extradural clot exists, look out for the middle meningeal artery. Remember that it runs in a deep groove on the inner surface of the cranium, and that in trephining directly over it, unless the dura be separated in some way from the cranium, the artery is likely to be cut by the trephine before the bone has been completely sawn through. Again, remember how closely the dura is or may be attached to the inner surface of the cranium, and that in cutting with bone forceps in the course of the artery or its branches, great care must be taken not to tear or cut the blood-vessel.

(5) It is perhaps scarcely necessary to mention that all cases of intracranial hemorrhage with which the surgeon has to deal (that is, all cases from superficial vessels, from sinuses, etc.) can be stopped by pressure. Ligating the vessel when possible is preferable, but sometimes it is not possible.

(6) The last point I wish to speak of is a somewhat doubtful one in my mind, and I only desire to call your attention to it. This is the length of time during which packing should be left in the intracranial cavity. I am inclined to think that the present tendency is to remove it too early.

Gentlemen: I thank you for your attention, and I hope that you will pardon my presumption in speaking on surgical subjects before a surgical society.

## ACUTE GONORRHEAL RHEUMATISM.[1]

BY HOWARD LILIENTHAL, M.D., NEW YORK,
*Assistant Surgeon to Mt. Sinai Hospital, etc.*

Gonorrhea with its various complications has, of late years, been the subject of much research by investigators all over the world. Much has been learned of the pathology and etiology of the various forms of the disease and of the life history of its determining organism, the gonococcus. We have been taught how to recognize the germs with the aid of the microscope, how to cultivate them artificially in all their virulence, and how to prove them to be gonococci by showing that inoculations of the urethræ of dogs with the culture is followed by gonorrhea (Turró). Cultures of the germs have also been obtained from the fluids and tissues of various parts of the body afflicted by inflammation coincident with gonorrhea elsewhere.

The subject of this paper is one of the complications of gonorrhea which, though unfortunately far from rare, has until very lately been so misunderstood that many have even gone so far as to doubt its existence. Some believe that the disease is usually due to germs other than those of gonorrhea, and they are inclined thus to regard it as a pyemia. Doubtless there are instances of mixed infection; and the examination of a few such cases will go far to form an individual opinion. Writers and observers are not wanting who take the ailment to be of nervous origin, vaso-motor in character (Lewin). It is hard to believe that any one educated in the modern way can reach such a conclusion. If the disease were a pyemia, we should more often see other signs of pyemia, such as multiple abscesses. This complication is, however, a very rare one; and when it does occur, it seems to be the result of an infection grafted upon the gonorrheal rheumatism, and not its cause or a coincident effect from a common cause. It is not in every instance practicable to give the "ocular proof" in this disease, but a good clinical diagnosis may nevertheless usually be made; and often in just such cases treatment is most needed, and the patients are most anxious for an opinion and prognosis.

My belief is that such a disease as gonorrheal rheumatism exists; that it is invariably caused by the gonococcus; and that in the most severe cases there is a group of symptoms so characteristic that one may repeatedly make a working diagnosis without even the corroborative evidence of coexistent gonorrheal urethritis. The discovery of gonococci in secretion or tissue is proof of gonorrhea; but the failure to discover them does not prove absence of the disease, especially if clinical symptoms be present. It has lately been learned that the germs may undergo changes of involution which result in forms of the organism quite unlike gonococci in appearance and in staining properties, and yet on culture and physiological test the usual forms are again evolved (see Touton).

The part played by the male urethra in the production of gonorrheal rheumatism has, I believe, been overestimated, and the frequency of the disease in females, underestimated. In these days of accurate investigation cases are not wanting where other mucous membranes have been the source of the rheumatic metastasis, for example, the conjunctiva (Kammerer).

Gonorrheal rheumatism has been classified according to the tissue involved, whether joint, tendon-sheath or bursa; and it may be acute or chronic. It is not, however, my intention to enter here upon an exhaustive description of the malady in its various forms, but rather to confine myself to its more acute and serious aspect from a purely clinical point of view.

Acute gonorrheal rheumatism is usually described as a mono-articular inflammation, with considerable pain, but not so much pain nor constitutional disturbance as is noted in ordinary acute rheumatism (Keyes). It is my belief that no inflammation causes more exquisite and demoralizing pain than the one under discussion. I have in several cases been able to guess correctly the nature of the trouble from this one symptom, and the history of its persistence for more than a few days. This, too, in spite of the wilful misrepresentations of the patients. Not long ago I saw a young man of nineteen who had been for about four weeks confined to his bed with an arthritis of the right knee. He had lost much flesh and strength. His temperature had been high (104° F.), but for some days had been below 101° maximum. There was great swelling of the knee, with evident disintegration of the joint. The entire neighborhood was boggy and semi-fluctuating. The gentleman in charge was an orthopedic surgeon, and I was called to give an opinion as to the advisability of excision of the knee. On approaching the patient I saw that he was completely demoralized. He shrieked with pain at the lightest touch, and had to be anesthetized to be properly examined. His physician had made up his mind that bone disease existed, and suggested that it had perhaps gone so far as to demand amputation. My diagnosis was gonorrheal arthritis, with destruction of the joint. This opinion I held principally on account of the peculiar character of the pain. The patient insisted that he had no gonorrhea, and this in spite of a suspicious

[1] Read before the "Warren Club," December 4, 1894.

moisture at the meatus. Mainly on account of this action on the part of the patient, an intelligent young man, I finally agreed to an exploration by incision. No pus was found, but the joint was filled with a gelatinoid mass of granulation tissue, the bones being perfectly healthy. An examination of the joint contents by a pathologist showed numerous diplococci, which that gentleman believed to be gonococci. Cultures were not made.

The case went from bad to worse, and finally came to amputation on account of general septic intoxication, the patient then making a rapid recovery. Autopsy of the joint showed disintegration of the articular and peri-articular structures, but with no bone involvement and scarcely any erosion of the cartilages. I believe excision of this knee would have been fatal.

Another instance illustrating diagnosis without immediate corroboration by the history of urethral blenorrhea is that of a physician of my acquaintance. I found on my table one day a note, the chirography very shaky, saying, "Call at once. Wrist lame." When I saw my colleague, he was in great pain, which had its principal seat in the sheaths of the extensor tendons of the right thumb, where I found a reddened sausage-like fluctuating swelling. The patient was a man of education, but of a phlegmatic, undemonstrative temperament, being usually one of the most insensitive of men as to physical pain; but now the mere pointing of a finger at the swelling made him nervous and apprehensive. There was also some pain in the wrist-joint, and there was a moderate elevation of temperature. I at once inquired whether or not the patient had urethritis, but met with an unqualified and emphatic denial. The arm and hand were put upon a flat splint, and treatment with oil of wintergreen and soda bicarbonate was commenced.

The progress of the case was slow and in a short time I was, in spite of the doctor's word to the contrary, quite sure of the character of the disease. Recovery was finally completed; and some months afterward my patient confessed that he had had a first attack of gonorrhea, and that two days before the rheumatism set in and, while the urethritis was still acute, he had cut his own meatus — an interesting fact because of the probable connection between the rheumatism and the trauma.

Gonorrheal rheumatism is not usually mono-articular, though occasionally a single joint is involved, and there is nearly always more or less disease in the neighboring tendon-sheaths and bursæ. This circumstance is probably the explanation of Charcot's three points of tenderness when the knee or the ankle is involved. These three tender points are almost pathognomonic of gonorrheal infection. They are all in the sole and at the spots where the body weight is principally borne; one at the heel directly under the calcaneum, one under the head of the first metatarsal, and one under the head of the fifth metatarsal. This tenderness makes a characteristic clinical picture. It is due to inflammation of the bursæ situated in the above-mentioned places. Another bursa, the retro-calcanear, between the calcaneum and tendo-Achillis is also commonly the seat of pain, constituting the majority of cases of so-called Achillodynia (Touton).

One important factor in the determining of an attack of rheumatism is direct injury to a part by a blow or strain. The symptoms in the second case cited above, for example, came on the morning after rather long-continued billiard practice, when the very group of tendons involved was excessively exercised. This is rather a rare region to be the seat of gonorrheal rheumatism; but the patient had, very likely, invited the onset of the trouble by incising his urethra, and the overstrain merely determined the location of the rheumatism.

Whenever, after a contusion or fracture, there is excessive, long-continued and increasing pain, with elevation of temperature, this complication should be thought of, be the patient male or female.

The diseases nearest resembling gonorrheal rheumatism are acute articular rheumatism and surgical tuberculosis. The principal clinical differences between gonorrheal and acute articular rheumatism are that in the ailment under discussion there is an absence of that profuse acid-smelling perspiration which characterizes ordinary rheumatism; that the pain is decidedly more severe; and that, although several regions in succession may become infected, there is no abatement of symptoms in those first diseased. The three points of tenderness in the sole, if knee or ankle is involved, and the slow instead of rapid improvement under salicylates, completes a sufficiently characteristic picture. The presence of endocarditis is not sufficient evidence to exclude gonorrhea as a cause, for recently cases of gonorrheal cardiac affections have been reported. Indeed, gonococci have been found by Councilman in the myocardium and pericardium; while Chiasso has, in a case of rheumatism, found them in the pleural cavity.

In the male the presence of sexual blenorrhea with gonococci is additional and weighty evidence, though not conclusive without the rest of the clinical appearances, for there is no reason known why a man with clap may not have ordinary rheumatism. In the female this corroborative evidence is often wanting, or with difficulty secured; for the discharge may be in the vagina, cervix, uterus, or even in more remote regions. It is always best to make a diagnosis in this disease without probatory puncture, though if there is question as to the advisability of operative procedure, this precaution should not be neglected. One unpleasant characteristic of the malady is its resentment of surgical operative interference. Trauma is one of the determining causes of an attack, and a joint which is becoming quiescent preparatory to a peaceful anchylosis may on forcible breaking up of adhesions, or on incision, become violently inflamed, and then progress, in spite of all treatment, to a termination fatal to limb or even life. In making the puncture it is best, in addition to the usual precautions, to make a minute incision through the skin with a scalpel, and then to insert the aspirating-needle so as to avoid passing the instrument through a possibly unclean skin and carrying the infection to the deeper parts. This exploratory puncture is most often required in those cases which have become chronic, where there is perhaps a vague history and no urethral discharge, and where other disease may be suspected. If the puncture into a much distended and fluctuating joint yield pure pus, I have learned to regard the case, especially if of short duration, as decidedly hopeful, not only as to the speedy recovery but also for a movable joint. Of course, thorough drainage is indispensable. I believe this class of cases to be usually due to mixed infection. Gonorrheal rheumatism generally fills the joint and

its neighborhood with plastic exudate, not pus, just as in the gonorrheal peritonitis so often met with in the female pelvis the exudate is more often solid than purulent; and this is in very clear contrast with peritonitis of the ordinary septic type where there is, as is well known, much pus formation.

The prognosis in all the more acute gonorrheal rheumatisms is grave. Even with the greatest care the inflammation may go on to the destruction and anchylosis of joints, or even to a general septic intoxication necessitating, as in the first case here mentioned, the most incisive measures to preserve life. To be sure, the disease may become chronic, and turn into a more or less quiet form of hydrarthrosis; but even here there often are exacerbations and perhaps infection of another kind. It is probable that such a joint may later become tubercular.

And now as to treatment. Unfortunately, although the science of medicine has made great progress in the last quarter-century, the noble healing *art* has hardly kept the pace. Yet to know the cause of an ailment is surely the first step in the right direction; and as in the past the discovery of a cause has always led to more intelligent and satisfactory therapy, so in the near future we may hope for a method for the cure of gonorrheal rheumatism. Up to the present our knowledge of treatment consists mainly in knowing what not to do. To be sure, various drugs, such as mercury, potassium iodide, the salicylates, alkalies, oil of wintergreen (itself salicylic), and many others have been proposed and tried. I must say I have a preference for oil of wintergreen and soda bicarbonate, with considerable attention to the use of the alkalies. Though Finger says that alkali predisposes to cystitis and that the weak acid of the normal urine kills the gonococcus, I seem to have one argument for my treatment in the recent investigations of Turró, who has found that though the germs will grow on alkaline human blood-serum, and will not grow on alkaline agar or gelatine, an excellent and virulent culture may be obtained from acidulated or unneutralized media, and that the urethræ of dogs may be infected with this culture. I shall, therefore, continue the alkali treatment until it has been really shown to be harmful or useless. Drugs aside, however, the diseased joint should be at once put at rest on a splint of such proportions that as much comfort as possible may be obtained. Gentle compression over a dressing of ichthyol ointment (20 per cent. to 50 per cent.), or over mercurial ointment, or over an ordinary wet dressing should be applied by bandage. The urethra or other focus of infection should be carefully treated, and the discharge decreased. The bowels should be regulated, and a minimal quantity of opium used. If the disease seems to be manageable, gentle massage is valuable during convalescence; but if anchylosis is believed inevitable, it should be assisted by perfect fixation in plaster-of-Paris. These patients usually become much run down by the disease, and should have from the first tonic and stimulant treatment. The so-called urethral hygiene, with starvation diet, will here do far more harm than good; on the contrary, the indication is for forced feeding. Meat, eggs, milk and its preparations, besides other simple and easily digested food, should be forced upon the patient every two hours or oftener. In many cases small doses of alcoholic stimulants will be well borne. An accurate record should be kept of all nourishment taken; it is more important than pulse or temperature. Lastly, avoid, if possible, all operative procedures. Abscesses must, of course, be evacuated; but do not be deceived by appearances and interfere in the acute stage for any other reason. This rule applies to those violent forms of the disease which are the subject of this paper, and does not refer to the later conditions of chronic deformity where gonorrheal rheumatism as such no longer exists.

For the sake of emphasis I have reserved the discussion of prophylaxis until the end. This part of the subject may be divided into two portions, namely, the prevention of gonorrheal infection and the prevention of the complication of gonorrheal rheumatism in those already infected. With the first of these heads I shall not here concern myself, because in all its aspects it has been often and thoroughly discussed. On the second head, however, the prevention of the complication in those already having blenorrhea, I wish to say a few words.

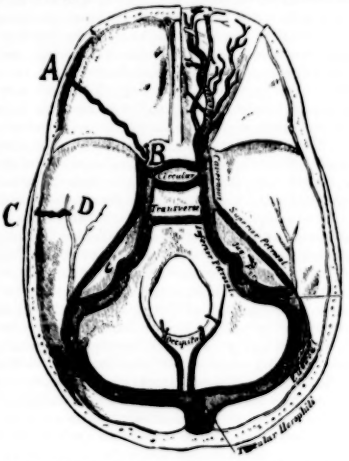
Knowing that the acquisition of a clap is a great misfortune, and that it is the sole cause of many and serious complications, I believe in an abortive treatment whenever this promises success. To my own satisfaction I have proven that if properly carried out the abortive treatment of clap may succeed, and without danger of aggravating the disease. Given a case of very short standing, where the discharge consists of mucus with some pus cells, first examine with microscope for gonococci. Having found them and settled the diagnosis, the patient is requested to urinate. Now, take an endoscope of such size as will very easily enter the meatus, and having lubricated with a little glycerine, examine the first *half-inch* of the urethra by daylight, without inserting the instrument deeper than is absolutely necessary. If no line of demarcation be seen, remove the instrument; wash it, and insert it for one inch, and examine again. Probably now a more or less distinct line of demarcation can be made out between the diseased anterior part and the deeper healthy mucous membrane. Carefully wipe out with dry cotton on an applicator, and then apply thoroughly by means of another swab a ten-per-cent. solution of nitrate of silver. The swab must enter the urethra a little farther than did the mandrel of the endoscope, and all parts of the canal from this point to the meatus must be thoroughly touched. No cocaine should be used. The patient must now go to bed and take bicarbonate of soda in ten to fifteen grain doses every two hours, drinking water at the rate of one six-ounce tumblerful every hour. The following day the discharge should again be examined; and if gonococci be found, another endoscopic examination should be made. If the diseased area extends deeper than before, it is not worth while to repeat the treatment, but otherwise silver may again be applied. If the germs vanish and then reappear in small numbers a day or two later, the application may be again made. It has been my fortune to try this treatment only twice, but both men were cured so promptly, all symptoms disappearing within two days, that I shall follow this method in other suitable cases. If it is to succeed it must be employed very early, for gonococci make their way rapidly to the deeper parts, von Crippa having found them in the fluid of the edematous tissues around the frenum five days after the attack began.

I am well aware that the abortion of a clap by means of argentic nitrate is a very old method. I also know that in one or another form it has been often

tried and often abandoned. The old method of injecting the silver is certainly dangerous, because if there is a failure to abort the malady we have caused a chemical irritation of a considerable portion of the urethral canal with a consequent catarrh, which makes the mucous membrane especially sensitive to attack by microbes. The endoscopic tube, however, renders it possible for us to confine our attentions to the diseased portions, and if properly used the method cannot be blamed for an aggravation of the gonorrhea.

It is not necessary for me to say anything concerning the local treatment of an ordinary clap; but, as in gonorrheal rheumatism, I believe that strict "urethral hygiene" may be overdone and too little attention paid to the patient himself. Locally, as in all acute inflammations where an antitoxic remedy is unknown, we must depend upon rest and the healing power of Nature. Meantime, however, by good food and plenty of it we may help our patient to resist the systemic intoxication with its anemia and general lowering of the vital forces which results from absorption of the poison generated by the gonococcus.

## Clinical Department.



### A CASE OF FRACTURE OF THE BASE OF THE SKULL, INVOLVING THE CAVERNOUS SINUS; OPERATION; RECOVERY.[1]

BY F. S. WATSON, M.D., BOSTON.

T. H. O'N., nineteen years old, was struck on the head by a brick thrown from a height of twenty feet above him. He fell, but immediately arose, again falling on his knees, however, an instant afterward. He then got up and walked across the street, and was, he says, fully conscious for one hour; the only pain he felt was in the right eye and above it. At the end of an hour he gradually lost consciousness, and knew nothing until the following morning.

He was brought to the hospital three hours after the accident, and was seen within the next half-hour by Dr. Bullard, whose record of his condition is as follows: "The patient is unconscious, but can be roused so as to make motions with the limbs. There is no hemorrhage from the ears, nose or mouth. The left pupil is dilated and does not react; the right pupil is normal. There is slight paresis of both extremities of the right side. Sensation is universally dulled, but this is thought to be due to unconsciousness. The knee-jerks are present and normal. Pulse 60, and of fair strength. During the next half-hour the paresis of the right extremities steadily increased, and the patient became more profoundly unconscious."

*Operation.* — A very slight, simple depressed fracture could be felt an inch to the left of the median line and just anterior to the coronal suture. The site of injury was exposed by a large semicircular incision and reflecting a skin-flap. All hemorrhage was prevented by transfixing its base, previous to incision, with a strong needle set in a handle (the needle being about eight inches long), and compressing the base of the flap with a piece of stout tape passed around it and drawn tight on the shaft of the needle. This familiar manœuvre of cutting off the blood-supply by transfixing the base of the flap serves a good purpose when applied to the skin-flap made to expose the cranium by saving time. The skull was trephined over the site of a very slight depressed fracture. A large blood-clot lay beneath the opening. The fracture was seen to extend in two radiating lines towards the base of the skull, anteriorly to the outer angle of the orbit and laterally downward toward the petrous portion of the temporal bone. On removing the clot beneath the trephine opening, profuse hemorrhage occurred. A channel half an inch wide was rapidly cut through the bone along the anterior line of fracture toward the outer angle of the orbit, with a rongeur, and was enlarged at its lower end. A large blood-clot was then seen to occupy the whole temporal region and to extend forward and backward beneath the base of the brain. On removing the clot the patient's respiration, which had become very slow, shallow and irregular, at once resumed its normal character. The finger could now be swept over the orbital plate, and the line of

AB and CD show the lines of fracture on the inner surface of the skull. (Gray's Anatomy.)

fracture could be clearly felt extending diagonally across it to the sella Turcica. From this point arose a profuse hemorrhage, which so far as could be determined originated at the point of junction of the ophthalmic vein and cavernous sinus. The bleeding from this place was controlled by firm packing with iodoform gauze. The posterior radiation of the fracture could also be clearly followed from the depression on the vertex well down toward the petrous portion of the temporal bone. From this region also a brisk hemorrhage was going on, probably from a branch of the middle meningeal artery. This was likewise controlled by firm pressure with iodoform gauze. The ends of the gauze were led through the lower end of the opening in the skull, and through a counter-opening in the base of the skin-flap, the edges of which were united with silk sutures. The packing was not removed until the tenth day. The patient made a rapid and uninterrupted recovery. On the morning following the operation he was perfectly intelligent, had no pain or other symptom. In twenty-four days he was out of bed, and

[1] Read before the Surgical Section of the Suffolk District Medical Society, December 5, 1894.

left the hospital on the twenty-eighth day, well. Other than weakness and some pain over the left eye and across the forehead, he has suffered no inconvenience since. He has, as you see to-night, the appearance of good health. He tells me, however, that on trying to resume his work two days ago he was obliged to give it up on account of being dizzy and easily flustered. (The patient was shown to the Society.)

## A CASE OF FROG-SKIN GRAFTING.

BY GEO. SEELEY SMITH, A.M. M.D., PROVIDENCE,
*Interne, Rhode Island Hospital.*

THE restoration of the integrity of the skin through grafting will always prove of interest to the medical profession, restoring, as it does, the epithelium of the part, and thereby preventing the deformity, and loss of function which would follow if the process of granulation were allowed to mature.

The following is the report of a case where both human epidermis, and the skin of the frog, were used for the purpose, and in some ways it is one of peculiar interest.

Necessity compelled me to look about for a substitute for human skin, and it was fortunate that my resources were thus taxed, for the subsequent course of the case showed that frog-skin not only *took* in a larger percentage of cases than human skin, but that its ultimate growth and proliferation was more rapid.

In August of 1893, while in Cleveland, O., I was *called* to see a case of very deep and extensive burn in a child five years of age. On July 18th, four weeks previous to my first visit, the boy's clothing caught fire, and before the flames could be extinguished the entire thickness of the skin had been destroyed over a large area of the trunk, face and neck.

The part involved may be traced by a line running from the thyroid cartilage, down the median line of the body to within an inch of the umbilicus, and from here following the band of the trousers around to the median line of the back; up to the external occipital protuberance; to the malar bone, on the left, including a portion of the ear; diagonally across the face to the right corner of the mouth, and completing the area by connecting this point with the thyroid cartilage.

I found the entire surface covered with healthy granulations that bled freely upon the slightest touch. In other respects, however, the case had received but little attention, a fact which was emphasized by the fold of the axilla being firmly adherent, through neglect to separate the parts in dressing.

As a consequence the arm was firmly bound down, and my first care was to break up these adhesions under ether.

It being evident from the first that healing by granulation would not only require many months, but would eventually result in considerable deformity, it was decided to resort to grafting. Here the first difficulty presented itself, as the surface was so extensive, and the boy in such a weak and nervous condition, that any attempt to have taken the necessary epidermis from him would have been highly imprudent.

It being very difficult to secure human contributions, I finally determined to resort to experiment, and frog-skin was tried, with the gratifying results already alluded to — results far beyond my fondest hopes.

On the 29th of August, operations were begun by planting upon the chest twenty pieces of skin, each a quarter of an inch square. They were placed in two rows of ten each, each graft being separated from its neighbor by a space of half an inch. In two days the skin had become identified with the granulating surface, and in five days the grafts had lost their original color, and each had sent forth embryonic epithelium meeting that of its neighbor.

This gave to the surface much the appearance of tile work. The embryonic epithelium was transparent at first, giving to the granulations underneath a slightly glazed appearance. In time this epithelium lost its transparency and then assumed the character of normal skin. In the course of a week the original grafts were dissolved leaving, instead, an embryonic epithelium such as has just been described.

Pieces were taken from the belly and legs of the frog, and also from the *back*, in cases where the frog was small, and the skin not too thick. In every instance the skin lost its original color in from five to ten days. It was found that the comparatively thick skin from the *back* took more satisfactorily than that from the belly or legs.

The case was dressed and grafted every second day, and on each occasion from twenty to eighty frog-grafts, and from ten to twenty human-grafts were used. The latter were very small (about one-sixteen of an inch in diameter) and were placed upon the face and neck until it became evident that the frog-skin would not retain its color.

The method used in dressing was as follows: The surface was first cleansed by irrigating with a warm solution of carbolic acid (one to forty), and after the detritus had been entirely cleared away the parts were washed with a stream of sterilized water. The latter step was to assure asepsis, grafts not thriving under conditions of antisepsis. Each graft was then firmly pressed into the granulating surface. Following this, a dressing of boric acid and vaseline (a drachm to the ounce) was spread upon strips of compress cloth, and applied so as to fit the parts snugly. Outside of this was placed sterilized gauze, and as a final step the roller bandage was used.

At first an attempt was made to hold the grafts in place by strips of gutta-percha; but it was soon found to be impracticable, as the surface was so extensive, and the child so nervous it was impossible to keep him still. The method employed although not so elegant proved effective, and few grafts were lost.

On October 5th, seven weeks after my first visit, the parts were all grafted in; nearly a thousand frog-grafts and about four hundred human-grafts having been planted. The skin, however, was soft and immature, and required constant care and dressing for three months thereafter.

The child attended school during the following spring, and at the time of the present writing (December 12th), has entirely regained his former robust health. He is able to throw his burned arm vertically over his head with no apparent effort. There is absolutely no contraction, the arm being full size where the burn encircled it.

I have recently seen frog-skin used in another case with very gratifying results, and I strongly recommend it as worthy of trial in cases where the destruction of skin is extensive, and it is deemed imprudent for the patient to furnish the epidermis required for the operation.

## AN ENDEMIC OF DIPHTHERIA APPARENTLY STOPPED BY THE USE OF ANTITOXIN.

BY F. GORDON MORRILL, M.D.,
*Visiting Physician to the Boston Children's Hospital.*

DURING 1894 there were three outbreaks of diphtheria at the Children's Hospital which rendered the institution worse than useless so far as the wards were concerned. Applications for admission had to be refused. Those who had the disease were transferred to the contagious wards, and all the other children were hurried away to the Convalescent House at Wellesley or to their own homes. The wards in which the cases had occurred, together with the furniture and bedding underwent the usual process of cleaning and disinfection, involving much trouble and expense, aside from the grave inconvenience of having the working of the hospital thrown out of gear for days at a time. The statistics of the disease were very unsatisfactory, as they have been everywhere previous to the use of antitoxin. It has also been very unsatisfactory, to say the least, to have a child enter the house for the purpose of having bow legs straightened or an eczema cured, and then die of a diphtheria contracted in the wards. It was thought at first that the disease was brought in by the parents and friends of the patients, and blouses and other precautionary measures were made obligatory to such visitors, in the hope of rendering them (externally) sterile. But in spite of these measures the thing recurred, and an active investigation (which is now in progress) will result, I think, in remedying certain faults in the ventilation, and thus reduce future danger to a minimum. The disease has apparently originated every time in one particular ward. But be this as it may, the result has always been the same; for all the children who were well enough to walk or even to be carried to the top of the building met in the playroom every day, and medical and surgical patients have suffered alike.

The cases were usually ill-defined at the start; a child suffering from what was apparently nothing more serious than a cold in the head or a mild tonsillitis would fatally infect others, or perhaps suddenly develop well-marked diphtheria in his or her own throat. In December there were two mild cases, both of which I injected with antitoxin, and would have then used the remedy throughout the wards as a prophylactic if it had been obtainable; but everybody at that time was hard pressed to obtain a sufficient quantity for a single case in private practice.

January 13th, eight days since, there were nine cases in the contagious wards, three of which were serious. During the preceding forty-eight hours there had been four or five cases sent over from the house, and the outlook was anything but cheerful. It was not my term of service; but as the staff very kindly gave me *carte blanche* in the emergency, I took charge so far as the diphtheria was concerned, and used antitoxin very freely and with particular reference to its immunizing properties. Every patient in the house was given an injection of five cubic centimetres of the serum prepared by the Pasteur Institute of New York, and admissions were continued with the proviso that each child should be given a like amount upon entrance. The patients in the contagious wards have been sent back to the house after being disinfected whenever they have shown two negative cultures three days apart. No fresh cases have occurred; and if we may judge by the history of previous outbreaks in the hospital, the present condition of affairs would appear to be the very satisfactory effect of a perfectly defined cause — it being the opinion of the staff that if protection had not been afforded the hospital would have been temporarily closed before now, and for the fourth time within twelve months. The patients who received the dose for immunity were suffering from various ailments, medical and surgical. No exception was made for any cause. In all 50 were injected, including those in the contagious wards. Three nurses and 39 children were injected for immunity. The ill effects were unimportant: well-marked urticaria on the fifth or sixth day in four; ephemeral diarrhea within twenty-four hours in seven; temporary increase of micturition in nine; anorexia and slight vomiting in four; well-marked tenderness over site of injection and extending up to axilla in two; erythema around the puncture in three. All these minor evils disappeared promptly. In some cases an increase of appetite and immediate improvement in general condition was noticed by Mr. Herbert J. Hall, the surgical interne, to whom I am indebted for good work in connection with the subject of these very hasty notes. These were mostly suppurative cases — spine and hip. Some very sick children were injected. In the surgical wards the serum was given in the evening (in many cases as late as 11 o'clock).

In no case to which I shall refer was the temperature normal when the injection was given. The surgical charts show an average temperature of 99.8° F. Four hours later it was 99.4°, the slight drop being accounted for by the hour (between 12 and 3 A. M.) at which it was taken, when the minimum would naturally be reached. Of those who showed a reaction (21 cases), the thermometer registered an average rise of .7° ten or twelve hours after the injections, and this in the morning when in children sick from other causes, the temperature would naturally be lower than in the evening. The greatest rise in any case was 1.8°. In one there was a drop of 2.8°; in one of 1.2°; in another of 4°. In a single instance there was no change whatever. These four were spine or hip patients. In 19 of the cases which reacted the evening temperature averaged 99.6° — a remission of about .5° at a time when, in a sick child, a rise would usually be expected.

The temperature of thirteen medical cases injected for immunity was 99.4°. These were all treated in the afternoon. Four hours later the average was 99.5°. Of the seven who reacted, the morning temperature (say sixteen hours after treatment) showed a rise of a small fraction less than a degree — this at a time when it would naturally be less than in the afternoon. Two cases registered a drop of .4°, one of 1.4°, and another of 1.2°. In one case no change was noted. A lobar pneumonia who had just dropped to normal showed the greatest reaction so far as temperature was concerned, a rise of 2.4°; but it dropped back to 99° in the evening, and there was absolutely no disturbance of its general condition. The average evening temperature of the cases which reacted was 99° in the evening. In short, the reactions were unmistakable, and agree with what has been hitherto observed.

Of those treated for diphtheria in the contagious wards, there is not much to be said. Two of the sickest children were sitting up in bed and enjoying themselves twenty-four hours after receiving a dose of

15 or 20 c. c. In both cases the temperature dropped twenty-four hours after treatment—one from 104° to 101.2°, and the other from 100.4° to 100°. Both were "nasty" cases. The worst case was sent over with a croupous pneumonia and the worst kind of diphtheria. In addition, there was almost a suppression of urine and edema of face and legs. In all, 45 c. c. was injected in this instance; but the child died sixty hours after the first dose, the temperature showing little or no change until a few hours before death, when it dropped from 102° to 101°. At the autopsy a broncho-pneumonia (from infection by the staphylococcus) in the lung opposite the original trouble (croupous pneumonia) was found. It was very extensive, and would have killed in any case. It is the only instance of an unmistakably double infection of the kind that I have ever seen or heard of. The mild cases have all done perfectly well, and three have been disinfected and returned to the general wards. There were no urticarias noted in the contagious wards.

## Medical Progress.

### RECENT PROGRESS IN DISEASES OF THE NERVOUS SYSTEM.

BY PHILIP COOMBS KNAPP, A.M., M.D.

#### DISTURBANCES OF SENSATION IN VISCERAL DISEASE.

HEAD[1] has concluded the very suggestive study analyzed in the last report,[2] with especial reference to the pain and tenderness in the head and neck produced by visceral disturbances. It is impossible in a brief analysis to do justice to these two papers, but they should be carefully studied in the original by all who desire to attain accuracy in the diagnosis of disease. In the first place by careful study of the distribution of pain and tenderness he differentiates seventeen areas in the head and neck, and he finds, as in his previous study, that the distribution of herpes zoster corresponds in the main to these areas, although on the face and head there is a much greater tendency for the eruption to appear over a group of several areas. The lower areas correspond to the sensory distribution of the third to the eighth cervical segments of the cord, and they overlap somewhat. Head next points out the areas rendered painful and tender by lesions of special organs of the head and neck. In affections of the eye, the headache produced by errors of refraction is associated with pain and tenderness in the mid-orbital region, it is definitely made worse by reading and sewing, it comes on in the morning as soon as the eyes are opened, it disappears under atropine when applied long enough completely to paralyze accommodation, and there is no pain or tenderness elsewhere. Disease situated deep in the cornea or anterior chamber causes referred pain in the fronto-nasal area; in the iris, in the temporal area; and farther back in the eye, in the temporal, fronto-temporal, and maxillary areas. The referred pain from diseased teeth varies according to the teeth affected, but in most cases Head has succeeded in establishing the area associated with each group of teeth. Disease of the external ear causes no referred pain; disease of the drum and middle ear causes referred pain and tenderness over the hyoid area; elevation of tension in the middle ear causes tenderness also over the vertical and parietal areas. Disease of the tongue causes tenderness in the mental, hyoid, and superior laryngeal areas. Furthermore, in disease of the various organs in the trunk there is apt to be referred pain and tenderness in the head areas as well as in the spinal areas, which the author in his previous article showed were associated with these organs. Thus in disease of the lungs there is apt to be referred pain in the fronto-nasal, mid-orbital, and fronto-temporal areas; in disease of the heart in the mid-orbital, fronto-temporal, and temporal areas; in disease of the stomach and small intestine in the temporal, vertical, and parietal areas; in disease of the liver in the vertical and occipital areas; in disease of the ovaries and testes in the occipital area; the uterus, the Fallopian tubes, and the bladder are not represented, and disease of these organs does not give rise to referred pain in the head. These areas do not correspond to the peripheral nerve-supply, which is found in the head to overlap tremendously. They probably represent some more central nervous arrangement than the posterior roots of the cervical plexus and main branches of the fifth nerve. All the thoracic and abdominal viscera which are referred into the dorsal areas of the scalp are supplied by the vago-glosso-pharyngeal nerve, which, as Gaskell has shown, represents the visceral branches of a set of nerves whose somatic sensory roots are to be found in the sensory portion of the fifth; so that it is not surprising that impulses passing up the vagus should be referred to the area of the fifth. The author's articles bear evidence of such careful and thorough work as to demand confidence, and the aid that a careful study of pain and tenderness in these different areas can give, seems to afford a new and valuable source of information in determining the diagnosis in cases of obscure disease.

#### NEURITIS.

*Beri-beri.*— Scheube,[3] whose earlier researches upon this disease are well known, has published an exhaustive study, which, in view of recent outbreaks of the disease in Dublin and occasionally on vessels, is of timely interest. He considers beri-beri a miasmatic infectious disease occurring chiefly in tropical countries. The special agent is still unknown, but it is to be sought in the soil; there are, however, certain individual and predisposing causes. Natives and colored persons are chiefly affected, men more than women; most cases occur between sixteen and thirty. One attack does not secure immunity. There are four forms of the disease: an imperfect, rudimentary form; the atrophic form; the dropsical form; and the acute, pernicious or cardiac form. The nervous system is chiefly affected, especially on the motor side; the legs and the peroneal muscles being chiefly affected. The cranial nerves are seldom involved, except the vagus, whose cardiac branches are especially apt to suffer. The paralysis is flaccid, and the muscles atrophy rapidly; symptoms of motor irritation also occur. There are various changes in the electrical excitability, sometimes amounting to complete reaction of degeneration. Sensibility in all its forms is diminished, and paresthesia is constant. The skin reflexes are normal; the knee-jerks are often absent. Cerebral symptoms are rare. Palpitation, cardiac distress and shortness of

[1] Brain, Part lxvii, 1894.
[2] See this Journal, Jan. 18, 1894.
[3] Die Beriberi-Krankheit, Jena, 1894.

breath are common; the pulse varies; functional heart murmurs are often heard. Anemia is frequent. There may be disturbances in the respiratory, digestive, urinary and genital apparatus, but these are less striking. There is very rarely fever. The patient usually recovers, the mortality not reaching five per cent. in his experience, but motor disturbances may persist. He gives the result of twenty autopsies. Dropsy is usually present, especially dropsy of the pericardium, and there are usually changes in the circulatory organs. The central nervous system is normal, but there is a degenerative inflammation of the peripheral nerves and of the muscles. The search for a specific bacterium has thus far proved unsuccessful. The disease is regarded as an endemic multiple neuritis. As prevention the author recommends good hygiene, a pure soil, good drinking water, and the erection of healthy dwellings. In the medicinal treatment of the disease digitalis has given the best results.

*Neuritis.*— An interesting discussion on peripheral neuritis was held last August at the Congress of Alienists and Neurologists of French-speaking countries.[4] Marie held to the opinion of Erb and others that the alterations in the peripheral nerves were dependent upon lesions provoked in the nervous centres by some morbid agent. If the peripheral origin of the alterations be assumed, how can we explain the symmetry of the motor and sensory troubles so often seen, or the incongruities in the localization of the trouble with regard to the nerve trunks — the segmental anesthesia, or the exemption of the supinator longus in lead paralysis? Furthermore, the atrophic paralysis of polyneuritis differs in no essential from the atrophic paralysis of anterior poliomyelitis. Anatomically, of course, the most profound changes are found in the nerves, but in polyneuritis the brain is often affected, and the latest and most exact researches are beginning to show lesions in the gray matter of the cord. The spinal ganglia have an important trophic influence upon the peripheral nerves, but very few observations have been made of them in polyneuritis. The lesions in the nerves themselves are often not in proportion to the symptoms; in many grave diseases, cachexiæ, and even in old age we may find changes in the nerves as great as in polyneuritis, without any marked motor or sensory troubles. The nerve roots may be apparently healthy, but this is not an argument against the central origin of the trouble, for the most peripheral parts of the nerve are the first to degenerate. Nevertheless the peripheral origin of some cases, notably leprous and vascular neuritis, cannot be wholly rejected, and an effort should be made to distinguish between the two forms.

Babinski distinguished two great classes of neuritis, those of external (usually traumatic) origin, and those due to internal causes, usually a toxic agent or a dyscrasic alteration in the blood. Only of leprous neuritis can we say that it is certainly due to peripheral causes. A very large number of cases, as Erb and Remak have shown in saturnine neuritis, are due to some slight alteration in the nervous centres. The axis-cylinder of the peripheral nerve is nothing but the prolongation of the nerve cell, and a disturbance of the central part of the cell, so slight as to be imperceptible, may in all probability manifest itself by changes in the parts of the cell farthest from the nucleus, that is, in the peripheral end of the axis-cylinder. Pathogenic agents may attack the whole cell, but only the most vulnerable part, the periphery, may show changes. Without one of these hypotheses it is difficult to understand certain forms of neuritis. We sometimes find lesions in the cord in cases presenting the symptoms of peripheral neuritis, especially in lead paralysis; but such changes may be seen also in cases of traumatic neuritis, clearly of peripheral origin, so that this argument is not decisive. The term peripheral neuritis should not imply that the lesions of the nerves are primary and the origin of all the trouble, and that the central nervous system presents no modification. It means only that the changes perceptible by present methods are located exclusively or chiefly in the peripheral nerves. Many of the pathogenic agents of neuritis cause disturbances both of the central and peripheral nervous system, and sometimes of other anatomical systems; the functional troubles due to them are caused not only by the perceptible changes in the nerves, but by dynamic changes elsewhere; the lesions of the nerves are only the most apparent alterations.

Renaut thought that the axis-cylinder, although a prolongation of the cell, must be considered as a highly differentiated member of it, rather than as a simple expansion. In the large amyelinic nerves of cyclostomes the axis-cylinder as it becomes a nerve quintuples in volume, and an abundant granular protoplasm takes its place between the fibrillæ; this is an active agent in nutrition. Perineuritis, Gombault's segmentary neuritis, parenchymatous and interstitial neuritis all point to a peripheral affection in many cases.

Pitres distinguished three classes of neuritis: local, due to cold, injury, or local infection (as in leprosy); general, toxic and infectious; and cases of central origin, as in poliomyelitis, tabes, hemiplegia, etc. The first two groups are due to alterations produced by the morbid agent on the peripheral parts; in the majority of cases they are primarily cases of peripheral neuritis.

Babinski called attention to the relations between tabes and peripheral neuritis, and held that the lesions in the posterior columns of the cord could not be proved to be secondary to lesions of the roots or spinal ganglia. Dynamic changes in the ganglion cells were merely hypothetical, yet we must assume them in tabes, optic atrophy, and other affections. Others hold that the affections of the nerves are primary, and that the cells may be affected later, by an ascending neuritis; but no case of neuritis of external origin has ever given rise to spinal lesions like those of tabes, and alcoholic, saturnine, or diphtheritic neuritis has never caused Duchenne's spinal atrophy.

*Psychoses of Neuritis.*—Colella[5] has made an elaborate study of the polyneuritic psychosis, based on a study of 35 cases, eight of which came under his own observation. In many cases of polyneuritis the psychical symptoms present a very definite clinical form. These symptoms are due to the same morbid conditions (toxic substances) which produce the neuritis. The psychosis, however, does not seem to have any definite relation to the severity of the neuritis. The psychical condition is represented by a particular mental state in which amnesia predominates. In one class of cases the disorder of memory may come on acutely, may be

[4] Congrès des médicins alienistes et neurologistes des pays de langue française. Archives de Neurologie, Sept., 1894.

[5] Annali di neurologia, xii, 1, 151, 1894.

more or less profound, may involve especially recent events, and may present itself almost as a state of isolation. In other cases, together with grave amnesia, disorders of consciousness, incoherence and restriction in the field of ideas predominate. In a third class phenomena of an exaggerated irritability in the psychical sphere predominate with the disturbances of memory. The psychosis may begin with a period of delirium and disorders of perception. After these have disappeared the disorders of memory may present the following characteristics: there is a profound, general, almost instantaneous amnesia of recent acts and impressions, contrasting with the detailed and precise account of more distant events; this amnesia may not only involve all memories subsequent to the onset of the disease, but also memories of the period immediately preceding; the absolute incapacity to recall present events is often in contrast with the precision of the patient's answers, the logic of his reasoning, and the justness of his conclusions; the amnesia is determined by the loss of the faculty of evoking memories, which conforms to the ordinary rule that the latest memories are the first to be lost, and that the affective faculties are lost more slowly than the intellectual. Recovery follows a similar process. Consciousness may be unaffected; but sometimes the patient has no consciousness of the place where he is, the people who are about him, or even of his disease. Ideation may be normal, but the range of ideas may be very limited. There may also be an exaggerated excitability and anxiety, sometimes approaching outbursts of mania. When the patient's general condition is good, and the cause of the disease can be removed, the psychosis usually terminates favorably, but when the evolution is very rapid and intense, and is due to a general and profound intoxication, and when it develops in debilitated subjects suffering from tuberculosis, cancer, etc., it is apt to result fatally.

Régis [6] in the discussion referred to above, does not admit that this psychosis is especially associated with polyneuritis, but thinks that they are both consequences of the same cause — intoxication or infection. He cites the case of a young man who, after diphtheria, had the characteristic mental state of the polyneuritic psychosis, but he had no neuritis until eight months later, when he had a mild attack brought on by cold. The infection may have left a protracted predisposition to the neuritis. The psychosis he believed to be simply an infectious psychosis, not necessarily connected with the neuritis, which is merely another effect of the same cause.

*(To be continued.)*

PRESSURE PALSY FROM WALKING UPON STILTS. — Bergonié and Bordier report a case of paralysis from pressure on the right anterior tibial nerve, just below the division of the external popliteal nerve into its anterior tibial and peroneal branches. The tibialis anticus and the extensors of the toes and the great toe were the muscles affected. The peronei had escaped. The patient lived in the marshy districts near Bordeaux, where the use of stilts is common, and walked several miles daily upon them. The stilt was buckled round the upper part of the leg by a stout strap, beneath which he wore a leather pad. It was this pad which had compressed the nerve. On the left side the pad fitted better, and the nerve had escaped injury.

# Reports of Societies.

## SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

C. L. SCUDDER, M.D., SECRETARY.

REGULAR Meeting, Wednesday, December 5, 1894, DR. F. B. HARRINGTON in the chair.

DR. F. S. WATSON read a paper describing

### A CASE OF FRACTURE OF THE BASE OF THE SKULL PROBABLY INVOLVING THE CAVERNOUS SINUS; OPERATION; RECOVERY.[1]

DR. BULLARD: I will just say one word on this case of Dr. Watson's. There are two points I wish to speak of. First, the size of the clot. The clot was very large. It extended as far back as could be determined and downwards towards the base of the skull. Between the orbital plate and the frontal lobe of the brain it was nearly an inch in thickness. In the second place, Dr. Watson compressed the middle meningeal artery near the pterion, and found that that did not stop the hemorrhage; consequently the hemorrhage was not due to the meningeal at or above this point.

Dr. Bullard also presented a paper on

### A CONSIDERATION OF SOME OF THE INDICATIONS FOR OPERATIONS IN HEAD INJURIES.[2]

DR. BRADFORD: The questions which Dr. Bullard has stated I think can be very briefly answered. In the first place, as to the size of the button. It seems to me that that depends somewhat upon the operation. If you are to remove a tumor of large size, you make the opening according to that tumor. If you are making an exploratory operation, it seems to me best to make an opening large enough for the rongeur forceps, in order that you may increase the size of the opening if necessary. As to opening the dura, I should agree with what Dr. Bullard says, that it should be treated as one would treat the peritoneum. One would rather not open the peritoneum when it is not necessary, but one would not hesitate to open it when it is. As to the length of time, it has seemed to me that speed is of importance, and it is for that reason that I feel inclined to use mechanical force in trephining, that is, surgical injuries. I have not formulated any opinion in regard to the length of time which packing should be kept in the skull. I know I myself have removed the packing too soon.

DR. ABNER POST: I can say very little except to agree in general with Dr. Bullard's propositions. In regard particularly to the size of the trephine, it seems to me that one should think rather of the instrument which will penetrate the skull the quickest than the exact size of the trephine. The larger the trephine the greater the mechanical force required to drive it, and a sharp instrument which is not exactly the size desired would be to my mind preferable to one of the exact size a man chose which was dull and would require a greater length of time, for time seems to me to be everything. There are very few skulls indeed in which the opening cannot be enlarged by the rongeur forceps after the trephine has once removed a single button. I do not think I ever met with but one skull where I was unable to enlarge my opening with ron-

[1] See page 78 of the Journal.
[2] See page 73 of the Journal.

geur forceps. My experience in regard to opening the dura would coincide exactly with Dr. Bullard's. I do not know as I have ever seen any trouble follow it, and I certainly have opened it a good many times. In regard to packing, I feel very sure that I have kept packing within the skull for a fortnight. In one case in which a longitudinal sinus was opened the packing required was pretty extensive to control the hemorrhage, and it was removed only gradually piece by piece. I am sure it was fully a fortnight before the last piece was taken out, and that patient recovered without any unpleasant symptoms. I should like to say one word a little outside of Dr. Bullard's line of argument, and that is in the use of the trephine in compound fractures. We speak invariably of trephining the skull in such cases, and I have noticed that a good many men who meet such compound fractures but seldom are a little surprised to notice that the trephine is not always necessary. A little judgment, little care, little use of the rongeur forceps in nipping off projecting points, or the elevator or forceps allows one to lift the depressed portion very rapidly without spending time with the trephine in a very large proportion of cases.

DR. RICHARDSON: I would like to congratulate Dr. Watson on his most brilliant case. I do not think I have anything to say with reference to the surgical questions Dr. Bullard has raised. I should agree with him in every particular, perhaps with the modification Dr. Bradford suggested of not opening the dura unless necessary. I think we should feel if anything does go wrong with a serous membrane, if any detail is neglected, — and we do once in a while even now see a drop of pus — I do — if we do get infection in a serous membrane like the peritoneum or brain, we have a deplorable result. As to the size of the trephine, I think one should be used which permits a rapid button formation, and yet not too large. I do not like the new trephines; they are built for the purpose of not slipping into the cranial cavity. I like the old cylindrical trephine. It cuts more rapidly, and one ought not to use a trephine if he cannot use it with sufficient skill not to suddenly slip into the brain. I usually use a trephine perhaps three-fourths of an inch in diameter. That is one I should select not only for the reason it acts more quickly, but with a very large trephine it is almost impossible to make a clean cut through the whole button; as there are very few parts of the bone where the thickness is the same.

I recall three cases in which opening the dura mater was followed by very extensive hernia cerebri, two were fatal at the end of some months; but it is only fair to say that there was a new growth in each pushing up the brain substance from behind. The third I reported a long time since; was septic; and I never understood why there was such extensive hernia. I should think one-half of the lateral lobe must have come out through the large opening, and the girl gradually became paralyzed and died. I do not recall the use of gauze to prevent hemorrhage in but one case. I never met that trouble from hemorrhage from flaps or other cause in cerebral operation except once, and in that instance it was controlled. The patient had a hemorrhage from the place Dr. Watson's came from. It was alarming. Dr. Brewster tells me he left the gauze in forty-eight hours. I think, as a rule, we are inclined to leave the gauze in too long, long enough to tear the newly-formed adhesions and to cause fresh hemorrhage.

DR. ELLIOT: I understand one of the points Dr. Bullard makes is that in these cases of patients unconscious after head injuries that opening the dura is a sufficient and very valuable procedure *per se*, even if neither blood or serum be found. This may be true, but his reasoning certainly fails to convince me. In the first place, if you take out a button where there is intracranial pressure, the dura itself gives somewhat and even bulges considerably where there is sub-dural blood; also in cases of brain tumor at the base, to relieve pressure we take out a button; we never open the dura in such cases; it relieves the pressure very much indeed without opening the dura. In these injury cases if you take out a button and open the dura, the brain itself does not bulge any more than the dura did; and so I see no advantage in opening the dura if there is no fluid under it. I often open the dura, yet I consider it a very important step in an operation. I think it is entirely different from opening the peritoneal cavity. In the peritoneal cavity things glue up rapidly and the peritoneal scar is not troublesome. After opening the dura, if you do a second operation, the brain is found glued to the dura and the dura glued to the skin, it makes a scar and a thickened mass which involves brain-tissue. Such a condition is objectionable, and should be avoided unless we are sure it is necessary. I know one case where a piece of the dura was cut out for epilepsy and there was relief for a year and then the convulsions returned; a secondary operation was done, and there was much more scar-tissue, much more of the condition which was originally found than at the first operation. The second operation brought only temporary relief, I suppose for the same reason. I often open the skull as an exploratory operation, and I feel I have not done any damage; but when I come to the dura I always consider carefully whether to go further. I think you can tell by feeling the dura whether there is any fluid under it. If there is fluid, you get the feeling of ballottement, the feeling of fluctuation. The dura does not necessarily bulge when there is blood under it. I have lately met a class of cases which is interesting to me. In these cases there is a compound depressed fracture, and the bone jammed into the brain, depression of half an inch or more. Take up the depression, and you feel the fluctuating dura, open the dura, and you find a condition of edema of the pia, perhaps a little bloody fluid, but not a great deal of blood. The pia seems to have been jammed and to have secreted a great deal of serous fluid. Of course, in such cases it is obvious that opening the dura is of value.

As to the time of the operation, I have usually felt there was no hurry, and I am governed entirely by the pulse and condition of the patient. I am surprised also in the indications for operation that Dr. Bullard has not laid more stress on the pulse. To me it is one of the most important things.

I think that packing in the skull cavity and especially in these large bleeding cavities ought to be managed with great care and great consideration. I do not think you can say it ought to be left in ten days by any means. I think in a general way packing ought to be left in if there is bleeding as long as it does not do any harm. It may cause pressure symptoms or even convulsions. It is extraordinary how gauze or a little pus in the wound or a little edema in

the flap outside the trephine hole affects the brain. I have seen such things cause convulsions so that it seemed as if the operation was wholly unsuccessful. When, however, the wound complication disappeared the case turned out all right again. So I think that although some cases do much better to leave the gauze in, it is not a general rule that should be followed.

Dr. Watson: I should like to speak for a moment in reference to the point Dr. Elliot has raised. It is the point Dr. Bullard brought out particularly and which I think he has focussed more clearly than Dr. Elliot. I am inclined to believe that some of Dr. Elliot's cases of pia edema are of that class of cases which Dr. Bullard described. This is outside the immediate line of discussion, but this question of acute edema following injury is very interesting I think. I had not heard it carefully described, or much importance given to it until Dr. Bullard called my attention to it last year. I had then two such cases, there was no intracranial hemorrhage whatever, but the patients showed symptoms such as arise from hemorrhage. On trephining and opening the dura, a considerable quantity of clear fluid poured out through the incision. The relief afforded by the evacuation of the serous fluid from the brain was very striking, and such as Dr. Bullard describes, and I cannot but think that in some of these cases, this acute edema is, as Dr. Bullard says, the important factor in the case; I do not know any neurologist who goes as Dr. Bullard has gone for years with the surgeons to all surgical cases of head and spinal injury occurring at the hospital, and I think great weight should be placed upon what he says as to this special class of cases after so large an experience.

Dr. Walton: I think Dr. Bullard is to be congratulated on his résumé of the subject and on the clearness with which he has brought his individual views before us. I am rather inclined, however, to agree with Dr. Elliot that we should not minimize the dangers of going through the dura mater simply because in a great many cases we fail to find unfavorable result therefrom. I have always regarded the dura mater as a danger point in the operation, not only on account of the greater danger of immediate injury, but on account of the other point alluded to by Dr. Elliot, that is, that after the operation is over the inflammatory products and the adhesions inside the dura pressing on the brain itself may become a source of irritation and set up convulsions in future time, dangers we do not incur when we leave the dura alone; and yet, though I regard it as a danger point, I should advise going through where there is any doubt. In advising this step I should not be guided simply by the question of pressure, a lesson impressed upon me by a recent case of Dr. Porter's in which there were undoubted signs of hemorrhage under the dura, convulsions on one side and deep coma coming on six days after the accident. In that case after going through the skull the dura was really depressed; it was far from bulging and it apparently pulsated, and there was considerable hesitation about recommending going through the dura. I was, myself, rather inclined not to advise it because there was no bulging and because there was apparent pulsation, and yet there was a slight lividity of the dura which influenced Dr. Porter to incise this membrane and disclose an extensive clot, which was removed, leaving the brain permanently depressed. That brings me to the point Dr. Elliot brought up regarding the cause of lack of bulging in some of these cases. In that case it looked as if the brain was really atrophied, partly perhaps from the loss of blood and perhaps partly from general circulatory defect. This is the first case of the sort I have seen, for in all previous cases of hemorrhage I recall the dura was bulging. About the size of the opening, I should not quite want to make a cut-and-dried rule that every opening should be at least two by one inches for example, or of any definite size. I think the trephine opening above will sometimes suffice for exploration, or tapping a cyst, perhaps; and I should be guided by the necessity of the case. If there is necessity for opening it, that is, if there is marked bulging, for example, of the dura mater, I would advise enlarging the opening extensively before going through the dura mater. I saw one case with Dr. Richardson in which there was a large glioma, in which the opening was made as we thought at first sufficiently large; but on opening the dura the brain poured out in every direction over the trephine opening so as to materially interfere with further enlargement. With regard to the question of time, I consider this factor often important, so important that I have favored in one or two instances the plan of Horsley, followed several times at the Massachusetts General Hospital, of first removing the bone, then allowing the wound to heal by first intention and several days later tearing it open and continuing the operation. This plan has worked very nicely in the cases I have seen.

Dr. Prince: I doubt if I can add anything of value to what Dr. Bullard has already said in his exceedingly interesting paper. I think his studies, if future observations shall confirm them, as I have no doubt they will, will prove to be quite an advance in our knowledge of the symptomatology of these cases, and will be a great help in the diagnosis and gives us valuable guides to operation. There is only one point on which I should like to speak, and that is on the usual surgical guides which are made use of by surgeons. There always will be, it seems to me, doubtful cases. You may lay down all the rules for guidance that you please, and there always will be cases in which you will be in doubt as to whether the hemorrhage is upon the surface or in the interior of the brain; as to whether there is hemorrhage at all, or whether it is a serous effusion; whether the symptoms are due to laceration or what not. Now, we may lay down all the rules we like, but in a practical consideration of these cases at the bedside I cannot help feeling that we must be in doubt at times, as I know I have been when called upon for an opinion in the past. The point I wish to make is this: it seems to me that surgeons have always been a little too prone to consider whether or not they should operate, to consider what the prognosis is regarding the life of the patient and to consider that alone. I think all neurologists here will agree that many of these cases afterwards turn up in the neurological departments of the hospitals and there come into the hands of the neurologist and their after-condition in many cases is pitiable. In such cases it seems to me we should also consider what the after-condition of that patient is likely to be. For example, we have a doubtful case, not quite certain as to the location of the hemorrhage if there is one. It seems to me that in such cases, even if we are not certain as to the advisability so far as life is concerned, that we ought to give the benefit of the chance to the patient

and operate if we feel certain we shall not do any harm, even although we feel certain he will get well. I have seen so many cases where the patient has been a wreck afterwards in life that I think that should be taken into consideration as well as the mere question whether or not the patient is going to get well. Only the other day, for example, I was called upon to give an opinion, and I advised operation. The surgeon was opposed to it, I think largely on the ground that the patient would get well. The patient did get well; but I am still of the opinion from the after-condition that the operation should have been performed, and I am not certain that he don't come to operation yet.

Regarding this matter of opening the dura, perhaps I should not hold an opinion, but I do think this, that it is a little mite risky laying down positive rules that it is perfectly safe to open the dura, because I think we can only say it is theoretically safe on the supposition that absolute antisepsis is obtained. I think we must take into consideration the results of other people's operations as well as those with whom we are conversant; and I think perusal of the literature will show that it is not very infrequent to have sepsis after the dura is opened, and even, as Dr. Richardson has said, he himself has had a case where sepsis occurred, and yet one cannot doubt that every precaution was taken. Therefore, while Dr. Bullard might lay down that rule theoretically provided absolute asepsis can be secured, it seems to me a dangerous rule to give the surgeon at large, and to say that anybody, no matter whether he is careful or not, his methods good or bad, can open the dura with impunity. It seems to me a little bit dangerous rule to lay down in that way.

DR. FOLSOM: I am very strongly of Dr. Prince's opinion that there is a very considerable number of cases where it is absolutely impossible to say precisely what is the source of the paralysis or of the pressure. I think in those cases it is justifiable and good practice to trephine, and if necessary to take out two or three buttons of bone, to make quite a large opening simply for the sake of making a diagnosis. That has been done in three cases in my practice in the last five years. In neither case did there seem to be any sufficient reason for going through the dura. Neither the family nor I should have been satisfied, considering the gravity of the situation, if in each case that much had not been done. If the dura is not opened, it is a simple operation and justifiable for assistance in making an accurate diagnosis.

DR. KNAPP: I feel very grateful to Dr. Bullard for his valuable and clear paper. I think he has put the rules for operation in these head injuries more concisely and more simply than has been previously done. As regards the indications for operating, I agree with him distinctly that we should be guided very largely by the indication of increased intracranial pressure; but I would also agree with Dr. Prince that there are a good many cases where it is better to operate even if it is not on account of the simple question of life or death. It seems to me that in every case where the symptoms are at all grave we should operate. I believe that it makes the prognosis only a little worse in such a case, that the risks of the ordinary trephining are very slight; and in those cases, as Dr. Prince has suggested, where there is possibility of local injury to the brain I believe that we should remove as far as possible early in the development of the case the source of the irritation.

I am glad to hear most of the surgeons agree in the question as to opening the dura, an opinion which I have held almost from my earliest experience in brain surgery. I have never yet been able, in what I have read or observed in the cases of trephining, to discover that opening the dura added materially to the risk. I think the case Dr. Walton has cited is just such a case. We might have had the record of the first operation for brain tumor in the world if the surgeon had been willing to take the risk of opening the dura. The last stroke of the operation was not done, and the tumor lay just beneath the dura. Certain risks in opening the dura must, however, be admitted. It adds somewhat to the risk of sepsis. There is also some risk, as Dr. Elliot has suggested, of setting up adhesions and possibly causing epilepsy. The chief immediate risk, as far as life goes, is the risk of brain hernia. That develops, I believe, under only two conditions: the first place, under septic conditions where for some reason, I know not why, there is the possibility of very tremendous hernia; and, secondly, in the cases of tumor, where the tumor cannot be removed. My own experience with trephining for the relief of pressure in brain tumors is that I have not got much relief to the pressure, until the ventricle was tapped; but I think that in every case of trephining for the relief of pressure of the brain tumor, you will be pretty certain to get brain hernia and death in the course of two or three months; I doubt if you get very marked relief for any length of time in those cases from opening the skull without opening the dura. The dura is usually so tense and so firm that it gives very little relief. The suggestion with regard to edema of the brain which Dr. Bullard has made, is of distinct interest. In cases of that sort it seems to me it is necessary to open the dura in order to get drainage. You get a little enlargement from the bulging of the dura; but the relief that is to be obtained is the relief by means of drainage — the drainage of the cerebro-spinal fluid or the edematous fluid which is causing the increased intracranial pressure. If you do not let that out, you do no good.

DR. LOTHROP: I would like to say just a word in regard to opening the skull. The ordinary method here is with the trephine, and then enlarging with the ronguer. Recently I have seen a good many cases where the skull was opened with the chisel and hammer, and in these cases you can make use of the line of fracture. First make an oval incision going through to the skull, not stripping off the periosteum, then chisel round on the bevel and turn down more or less of this bone-flap according to the size of the opening desired. You have at once a large field for operation, and it makes no difference whether the skull chips or cracks; simply remove all the spiculæ, and turn the flap back, and it has the advantage of being able to close the opening in the skull, whereas with the trephine and ronguer you have lost all the bone tissue. I think that this method has some advantages.

DR. ELLIOT: I should like to mention one case that bears on the point of opening the dura. I had a child two years ago; the top of the head was broken in by a severe injury, and the whole top of the skull taken out, and the dura was lacerated and brain lacerated in several different directions, so that the brain substance with blood was running out. In that case it seemed to me that the brain was fast oozing away, and I sewed up the dura tight with two lines of catgut suture with all the blood and degenerated brain

in there, and he recovered promptly, but had certain paralyses. In this case a very severe brain injury did well with the dura closed.

DR. RICHARDSON: In the case Dr. Prince referred to of hernia, the dura was opened for abscess. It was a case of sepsis previous to the operation. Moreover, the operation was performed in the antiseptic days in the time when the mortality from sepsis was great. I trephined last summer twice for brain tumor. In one instance it was for a glioma. In another instance I trephined over both lobes of the cerebellum in a child, and was able to see through the transparent dura the outlines perfectly of the convolutions of the cerebellum, and it was evident that there was no tumor there. The relief from pressure was so great that the child, from groaning and pain, became perfectly quiet, and was singing all the rest of the time in the hospital. I have been sorry I did not open the dura in that case, and explore with the finger all the lobes of the cerebellum; but not being able to feel or see anything, it seemed at the time that we had done enough.

DR. HARRINGTON: In connection with what Dr. Prince has said about the difficulty of deciding what to do and the importance of operating in certain cases where life is not threatened, but where the after-effects may be bad, I should like to mention a case which came to the hospital last summer. An infant of a few months was placed by its mother on the tail-board of a wagon. The horse being tied and being suddenly startled brought his chin down on the child's head. The result was a marked depression in the middle of the parietal bone as large as a silver half-dollar which might have held half a drachm of liquid. The child cried and suffered considerable pain at the time of the accident. There were no symptoms of pressure. I watched the case a week. The child seemed perfectly well. There seemed to be no change in the depression. It was a case in which one would have had very little difficulty I think in elevating the depressed skull, but it seemed to me that the condition was more like a green-stick fracture and that in time the development of the parts would correct the depression or that the pressure being regular and free from spiculæ, no trouble would ensue. Yet this was not the unanimous feeling of surgeons who saw the case. I have not since heard from the child and for this reason I judge that there have been as yet no unfavorable symptoms.

DR. G. H. MONKS showed a pair of Keen's rongeur forceps, which he had used successfully in one case, where it was necessary to make a very large opening in a child's skull.

DR. BULLARD: In regard to intracranial pressure, I consider that the most important symptom in determining in many cases the question of operation. In these cases we often trephine and find the dura bulging and tense and there is no pulsation. It is in those cases that I advise that the dura be incised. Of course there are certain cases in which the dura is not tense. They are not very uncommon. We may have tenseness of the dura and non-pulsation from hemorrhage beneath the dura or the pia; but as a rule the bulging in these cases is not due to hemorrhage apparently, but to simple swelling of the brain, because the moment the dura is cut the pulsation of the brain returns without fluid escaping with great rapidity from anywhere. But it is impossible to say absolutely what the cause of this condition is. All I know is that there is increased intradural pressure which does not appear to be due to hemorrhage. After the dura has been cut the advantage to the patient is very evident in many cases; of this there is no doubt. Patients are brought to the operating table comatose, with stertorous respiration and apparently in almost hopeless condition. I have seen such patients recover consciousness immediately after getting over the effects of the ether and retain that consciousness and go on to recovery.

With regard to the question of packing, Dr. Richardson, I think, said he had taken packing out in two days without any untoward effects. I have seen packing stay in eleven days and then removed without untoward symptoms. The packing may stay in sometimes for some time without producing untoward symptoms although the difficulty of removal is said to be greater when it stays in longer. On the other hand, I have seen packing put in and hemiplegia, partial paresis of the extremities, produced by that packing. Yet although the packing was allowed to stay in nine or ten days, the paresis passed off with the removal of the packing. In other words, the mere fact that paresis is produced by pressure of packing, does not in itself contra-indicate the leaving in of the packing for several days.

DR. BURT showed a specimen well preserved in a solution of formalin (1 to 40).

## MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

TWENTIETH ANNUAL MEETING, AT HOT SPRINGS, ARK., NOVEMBER 20-23, 1894.

### FIRST DAY. — MORNING SESSION.

THE Association was called to order by the Chairman of the Committee of Arrangements, DR. THOMAS E. HOLLAND, of Hot Springs.

An Address of Welcome on behalf of the State was delivered by GOVERNOR GEO. W. FISHBACK.

HON. W. H. MARTIN, of Hot Springs, followed with an Address of Welcome on behalf of the citizens of Hot Springs.

### PRESIDENT'S ADDRESS.

After the reading of the reports of the Secretary and Treasurer, the President, DR. X. C. SCOTT, of Cleveland, Ohio, delivered his address.

At the conclusion of the President's address, a committee of five was appointed to consider the suggestions contained therein and to report at a subsequent session.

### FIRST DAY. — AFTERNOON SESSION.

DR. EMORY LANPHEAR, of St. Louis, followed with a paper entitled

### BONE AND JOINT TUBERCULOSIS THE FUTURE FIELD OF LITIGATION AGAINST RAILWAYS.

He submitted the following conclusions:

(1) Pott's disease, hip-joint disease, white swelling, and most chronic joint affections are tuberculous, and "scrofula" has no existence, being but an attenuated tuberculosis.

(2) The family history is unimportant, as tuberculosis is always acquired — never inherited. The

presence of tuberculosis in the family simply gives a better opportunity for infection.

(3) Infection may occur in very early life. The germs lie dormant for many years in the lymph glands, and local tuberculosis only develops after an accident.

(4) An injury to a bone or joint must be slight in order to cause tuberculosis. If severe, the resultant inflammation or hypernutrition is not favorable to the proliferation of the bacilli.

(5) An injury *alone* can never produce tuberculosis. The bacillus must always be present in the system, or introduced into a wound at the site of injury.

(6) *Per contra*, bone or joint tuberculosis would never develop without a slight local injury.

(7) If after a railroad accident, falls, wrenches, or other accidents may possibly have occurred, the local trouble may be due to them as well as the railway injury. There must be a direct sequence to attribute the disease to the local injury.

DR. ROBERT H. BABCOCK, of Chicago, made some remarks on

ENLARGEMENT OF THE HEART WITHOUT VALVULAR DISEASE, WITH SPECIAL REFERENCE TO TREATMENT.

The reader said that idiopathic enlargement of the heart, as Fraentzel designates it, affecting primarily the left ventricle, is due primarily to prolonged, high arterial tension; and this increase of arterial tension may be secondary only to (1) a cirrhosis of the kidneys, (2) chronic arterio-sclerosis, (3) congenital narrowing of the arterial system, and (4) some obscure condition probably dependent upon defective assimilation and elimination, which is not fully understood, connected probably with the circulation in the blood of toxines. He wished to be understood as speaking of idiopathic enlargement of the heart without valvular lesions. Prolonged, high arterial tension he considered the chief factor concerned in the production of this form of enlargement of the heart. The enlargement may involve either the right side or the left side of the heart, or both. A case was reported in which the enlargement was primarily of the left ventricle; and the enlargement which existed on the right side of the heart was probably secondary to the dilatation which had taken place of the left ventricle. Prolonged, high arterial tension, when independent of organic disease of the kidneys or blood-vessels, seems to be due to what the Germans call "luxus consumption." It is observed in individuals who belong to the better class, who are more or less sedentary in occupation, who are hearty feeders, and oftentimes great diners out.

The treatment was divided into, first, the treatment of the stage of loss of compensation in which the heart is at first broken down in its resistance. Rest is the important factor, along with cardiac stimulants and the administration of remedies calculated to decrease the high arterial tension. The patients usually present themselves with dyspnea, cough, and frothy expectoration, and an extremely rapid and feeble pulse, with all the evidences of cardiac dilatation. Our first indication, therefore, is to relieve the over-distended left ventricle and to whip the heart on to increased vigor or contraction. Hydragogue cathartics are therefore indicated from the first, since their action is to lessen arterial tension; and by preference the author uses one of the mercurials, since the effect of calomel or blue mass is to lessen arterial tension even before its effects are manifested on the intestines, and this is followed by a saline.

Digitalis, strophanthus, and their congeners are not suitable to the cases in the stage of loss of compensation; since the effect of digitalis, and to a less degree strophanthus, is to increase the resistance within the arterial system, and thereby increase the strain, already too much for the impaired right ventricle. It is preferable to administer an arterial stimulant rather than one of the so-called cardiac tonics. Under the effect of rest and cardiac stimulants improvement in the condition is generally manifested speedily.

The author then referred to the Schott method of treating these cases, which consists of baths and gymnastic exercises. He stated that the treatment had been used in Germany for more than ten years. A combined course of baths and gymnastics is given for an interval of from perhaps seven or eight weeks. He considers this method of treatment suitable to all forms of chronic cardiac disease, excepting those in which heightened arterial tension would be disastrous, as in widespread and extreme chronic arterio-sclerosis, aneurism of the aorta or other large vessels, or cardiac aneurism.

DR. W. T. BAIRD, of Dallas, Tex., read a paper on

OXYGEN AS A HEART TONIC, AND SOME OF THE BENEFITS WHICH MAY BE DERIVED FROM ITS USE AS SUCH.

DR. W. H. DALY, of Pittsburgh, Pa., followed with a paper entitled

MALARIA A WATER-BORNE DISEASE.

The reader said, in summing up the evidence in a given case of so-called malaria, that it was important to remember that the water vehicles of malaria may include contaminated land-water, taken into the stomach on the stalks of celery or on the leaves of lettuce, or it may find its vehicle in the rinsing of milk-cans with malaria water or in the adulteration of milk with contaminated water containing the Laveran germ. The cistern-water stored under the earth may be easily contaminated by the earth-water containing the germ, if the cistern itself is cracked or otherwise inefficient. The fact that the patient has drank at all of suspected water, even but once, ought to be taken into consideration, as a single draught of contaminated water may have contained all the necessary germs for the infection of the blood and the production of the fever.

The author defined his position on this question by quoting from an article, published in the *Medical Record* of September 15, 1894, wherein he says: "Twenty years observations and studies on this subject, and investigations made in various districts from Manitoba to Louisiana, and all along the southern coast of the Atlantic Ocean, and of Cuba, Yucatan, and other districts in Mexico, lead the writer to the conclusion, that so-called malarial disease is not easily, if at all, contracted by inhaling so-called malaria or bad air, of the low, swampy or new lands, but it is distinctively, if not almost exclusively due to drinking the water that has come in contact with or become infected by the malarial germs or infusoria that exist in the earth and waters of the swamps and low lands. This germ does not ordinarily, if at all, float in the air during the day nor does it find easily a vehicle in the fog or vapors of the night."

SECOND DAY. — MORNING SESSION.

DR. A. P. BUCHMAN, of Fort Wayne, Ind., read a paper on

INTESTINAL INDIGESTION.

In conclusion the author said that any form of treatment instituted for the relief and cure of intestinal indigestion must necessarily include a careful consideration of the stomach and colon; that very little, if any, amelioration of symptoms will result unless they are both rationally included. Inasmuch as the colon is within easy reach *via* the rectum, it is the author's experience that colonic baths properly medicated are immensely useful in the general treatment and care of patients suffering with intestinal indigestion.

DR. J. E. WOODBRIDGE, of Youngstown, O., read a paper entitled

TYPHOID FEVER CAN BE ABORTED; ANOTHER YEAR'S WORK WITH NO DEATH AND NO FAILURE IN EVIDENCE.

This paper was in the nature of a supplement to the author's previous contributions on this subject.

DR. HENRY SUMMA, of St. Louis, read a paper on

OX-GALL IN THE TREATMENT OF TYPHOID FEVER.

The author highly recommended its use in this disease, and had obtained excellent results with it.

DR. A. B. WALKER, of Canton, O., discussed

THE IMPORTANCE OF URINALYSIS IN DIAGNOSIS.

If physicians and surgeons could avail themselves of this important aid to diagnosis, much more good could be accomplished to their patients, many a life spared, and thousands of dollars saved life-insurance companies. As urinalysis requires but a few moments of time, and the results from it are so positive and true, the writer felt that no opinion of a case of any importance should be given without there having been made a careful examination of the urine.

DR. A. M. OWEN, of Evansville, Ind., read a paper entitled

MY EXPERIENCE WITH GOLD AS A THERAPEUTIC AGENT.

DRS. FRANK R. FRY and M. A. BLISS, of St. Louis, presented a paper on

QUININE IN THE TREATMENT OF CHOREA.

The writers briefly reviewed Prof. H. C. Wood's theory of the causation of chorea as set forth in a paper on "The Choreic Movement," published in the *Journal of Nervous and Mental Disease*, April, 1893. They then reported a number of their own cases from clinic and private practice, in the treatment of which they have been using quinine. Their results confirm those of Dr. Wood and others. They called attention to the fact that they had not used as large doses as others, yet had had very satisfactory results. They raised the question whether the effect of quinine in this disease is due to the *modus operandi* suggested by Dr. Wood, namely, its stimulating effect on the spinal inhibitory apparatus, and not to some other effect. They suggest that this drug has a decided value in the treatment of certain infectious diseases, in which class, according to the opinion of some authorities, chorea belongs. While they have witnessed, decided, and, as a rule, only beneficial effects from the drug, in chorea they concluded that more data must be collected before its final status may be determined upon.

DR. EDWIN WALKER, of Evansville, Ind., read a paper on

REFLEX IRRITATION AS A CAUSE OF DISEASE.

The writer thought that no error in modern times has held such tenacious hold on the professional mind as that of reflex irritation as a cause of nervous disease. In fact, to most of us the explanation of the occurrence of any nervous phenomenon or lesion is satisfactorily accounted for if some peripheral irritation is found. A long prepuce, some slight version, flexion or laceration of the uterus or other deviation from the picture in our charts, is sufficient to account for hysteria, epilepsy, or other nervous disease. The reflex theory dates back many years. Early in this century it was offered as an explanation for certain neurotic phenomena; but its prominence in the medical mind of to-day is due to the lectures of Brown-Séquard on the "Physiology and Pathology of the Nervous Centers," delivered in London in 1858.

The essayist then alluded to the contributions of several other prominent writers in regard to reflex irritation as a cause of disease, and said that for nearly twenty years he had thought much of this question, his attention being first called to the articles of Sayre. He followed his advice and did many circumcisions, and later, mainly through the teachings of Emmet, did operations on the cervix and vagina, and has observed many cases of neuroses in women presenting various lesions of the genital tract; and states that he has never seen a case of epilepsy, insanity, catalepsy, hysteria, or grave neurasthenia, nor any organic disease of the nervous system cured or even permanently benefited by any operation on the genital tract, either done by himself or any one else. He has also noticed that a large proportion of patients who consult us for diseases of the genital tract do not suffer from definite nervous disease; and, on the other hand, that of patients who do consult us for nervous diseases, many and perhaps most of them are free from genital disease. In a given case in which we find genital irritation and nervous disease, a careful inquiry into the case will develop other more potent causes. The writer does not deny that lesions of the genital tract may not in some way derange the nervous system, but insists that it does not do so by reflex action. For example, a woman has a bad laceration of the perineum that interferes with her locomotion; it is difficult or painful for her to go about; her life becomes sedentary; she suffers with constipation, and later with dyspepsia, from her inactivity; then her general system suffers from deficient nutrition as well as the want of healthful exercise. The nerves are not nourished, and disease is engendered. Or a patient has some disease of the abdominal viscera; perhaps he has intestinal indigestion and nervous symptoms — a very common thing. Are we now to say that his nervous disease is reflected from his bowels? Certainly not. The lack of proper digestion and assimilation of food starves the system or by auto-infection poisons it.

*(To be continued.)*

---

LADY PAGET, the wife of Sir James Paget, died in London, January 7th, aged eighty years. She was married to Sir James Paget in 1844; their golden wedding was celebrated last year.

## GONORRHEAL INFECTION OF THE NERVOUS SYSTEM.

VARIOUS observations which have been recently published indicate that gonorrhea, like other infectious diseases, may give rise to secondary affections of the nervous system. Engel-Reimers [1] has collected four cases of multiple neuritis, two of which came under his own observation, which show that the toxines produced by the gonococcus may act deleteriously like alcohol or lead. A healthy man had gonorrhea, followed four weeks later by vesical symptoms. With these he had a gradual loss of power in the legs, and muscular tenderness. Ten days later the legs were wholly, and the arms were almost wholly paralyzed; the knee-jerks were lost; the electrical reactions were diminished; the sensibility was unimpaired; and the nerves and muscles were extremely tender. Later the face and larynx were involved. Convalescence was established in nine weeks.

A healthy girl was impregnated and infected one month before. The gonorrhea was followed by gradual paralysis, first of the arms and then of the legs, with pain, tenderness, and reaction of degeneration. She improved in five months, and was delivered of a healthy child at term. Engel-Reimers also thinks that there may be an isolated neuritis of gonorrheal origin, especially of the sciatic nerve, analogous to the multiple swellings of the joints, inflammation of the sheaths of the tendons, iritis, etc., due to gonorrhea; such a neuritis may vary in its severity with the gonorrhea. He also reports a case of acute spinal meningitis, and quotes two other cases. Gonorrhea alone seems inadequate to produce this condition, and some exciting cause, especially cold, seems also necessary. His own case was that of a young coachman, who had gonorrhea three weeks before, and who sat on his box in a severe north wind for several hours. He had a severe chill, sudden headache and backache, vomiting, fever, stiffness of the neck, herpes and erythema. The spleen was not enlarged and the sensorium was free. The spine was rigid. The headache and stiffness of the neck disappeared in forty-eight hours. The knee-jerks were exaggerated and there was much pain and tenderness over the vertebræ. Eleven days later the temperature fell, and in four weeks he recovered.

Tambourer [2] reports the case of a man who had chronic gonorrhea of three years' standing, associated with stricture, arthritis in the larger joints, and phlebitis in both legs. The phlebitis disappeared and the arthritis improved, but he had a sudden attack of cerebral embolism with right hemiplegia, and died in three days. The phlebitis and embolism were considered due to gonorrhea, Leyden having demonstrated gonococci in the vegetations on the valves in a case of acute gonorrheal endocarditis. Muscular atrophy and exaggerated reflexes were present, and were ascribed to the arthritis.

Pitres [3] supplements this by the report of two cases. A man with acute gonorrhea and arthritis had a sudden attack of apoplexy, with right hemiplegia and aphasia. Eight weeks later he had attacks of Jacksonian epilepsy and died. There was a large area of softening in the left hemisphere, and abscess of the kidney. The heart and vessels were healthy. Another young man with gonorrhea was attacked with left hemiplegia, from which he made a partial recovery. The heart and vessels were healthy. Pitres commits himself to no explanation of these cases, but states that he was simply struck by the coincidence of the two affections, especially so in the last case, in a man who had none of the ordinary causes of hemiplegia. He adds that if the observations multiply we may find that gonorrhea may produce softening of the brain, as it seems to produce myelitis.

Cullerre [4] reports the case of a woman with stupidity and hallucinatory confusion, symptoms of meningoencephalitis, and ideas of satisfaction and riches, which he thinks indicated an infectious psychosis. The only infection was by the gonococcus, but moral causes and possibly alcohol entered into the etiology, and provoked the explosion of nervous accidents prepared by infection. The second case had a bad nervous heredity; a young woman after gonorrhea, developed hallucinations, stupor, and outbursts of mania and melancholia.

Venturi [5] in twenty-two cases of hebephrenia found gonorrhea in twelve. It usually preceded the mental trouble, and none of the cases recovered until the gonorrhea was cured, the cure of the mental trouble usually coming two or three months later. Venturi thinks that there is a specific morbid process, a serous sub-arachnoid effusion provoked by the gonococcus.

[1] Jahrbücher der Hamburger Staatskranken-Anstalten, II. Jahrgang, 1890.

[2] Société de neurologie et de psychiatrie de Moscow, January, 1894, Revue neurologique, June 30, 1894.

[3] Revue neurologique, August 15, 1894.

[4] Vendée médicale, May 1, 1894.

[5] Riforma medica, Nos. 20, 21, 1894.

These latter cases do not seem very conclusive. Proof that the embolism is really due to any action of the gonococci is lacking, and, as Pitres says, the embolism may be merely a coincidence. In the reported cases of psychoses, gonorrhea seems to have been merely one factor in the etiology, and it is not unreasonable that the idea of having gonorrhea may have had a greater effect upon the brain than the gonococcus itself.

## REPORT ON NEW YORK TENEMENT-HOUSES.

THE New York Tenement-House Commission, of which Mr. Richard Watson Gilder is chairman, presented its report to the Legislature on January 17th, and it contains a large mass of information and numerous recommendations. The statements, we take it, are probably accurate. How far all the recommendations are possible and can be practically applied, time will show. The present situation unquestionably admits of great amelioration. The Commission found that New York, below the Harlem, had a greater density of population than any other city in the world, so far as known, namely, 143.2 per acre. In one down-town east-side district of 32 acres, there were found no less than 476.6 persons to each acre. After enumerating some of the evils of over-crowding, the report states that the "double-decker" tenement is the one hopeless form of tenement-house construction. It cannot be well lighted, it cannot be well ventilated, and even the High Street houses in Edinburgh, constructed centuries ago, are not so bad. Under the head of danger from fires the report says:

"In the year ending June 30, 1894, there were 2,415 tenement house fires, involving a loss of $608,784, and in that time fifteen occupants were killed outright and seventy-two injured. It is a startling fact that while less than one-third of the buildings in New York are tenement-houses, among them occur annually more than one-half of the fires."

Density of population, it was found, does not necessarily affect the death-rate, for the Tenth Ward, with its population of 621.66 to the acre, has a death-rate of only 17.14, next to the lowest in the city. The facts showed that soil and natural drainage have much to do with the death-rate, and the age and condition of buildings used as tenements affect it more than almost anything else. "It is a well-known fact," the report says, "that human dwellings, by prolonged occupation, become so saturated with the bodily emanations of those who have lived in them, sick and well, as to be less healthy than newer houses. This result of prolonged human occupancy is made worse in this city by the rapidity with which the character of the population in the lower parts of the city has changed, and the fact that houses built as private dwellings are not fitted to serve as tenements, either in respect to light, ventilation, water-supply, privacy or facilities for cleanliness. . . . The most cursory examination shows that the death-rates are very high where there are rear tenements; running up to 61.97 — an enormous death-rate — in the old First Ward, and being 27.66 for the entire city, against 22.21 for the single tenements. If we take the death-rate of children as a test, the rear tenements show themselves to be veritable slaughter-houses."

The report recommends an increase in the tenement-house inspection force of the Board of Health and also that the sanitary police force be augmented by fifteen additional inspectors. After referring to the necessity of parks in the tenement-house districts, and to a number of small parks which have been already ordered, the report goes on to say: "But supposing that the above parks were actually completed, what would be the situation of the most crowded part of the city as to breathing spaces? The area of the city below Fourteenth Street is 2,628 acres, or nearly four square miles. The estimated population of this area on July 1st was 707,530, the park area is 64.65 acres, or but 2.55 per cent. of the whole area, while the proportion of the park area inside the city limits is a little over 7.5 per cent. of the whole territory. . . . Not only should additional small parks first be placed where at the moment they are most needed, but in character they should be especially adapted to the local conditions. Each of these parks should have a considerable portion of its area — possibly not less than one-half — finished as a public playground, and one might be almost exclusively dedicated to such purposes."

The report states that, while the bathing habit is increasing among the masses of the people, out of a total population of 355,033 covered by the Commission's inspection, only 366 persons have access to bathrooms in the houses in which they live. "The freer use of water by the tenement-house population," it continues, "would aid them very materially in their struggle for existence by assisting the elimination from their systems of the poisons absorbed in the sunless and airless dwellings. That several hundred thousand people in the city have no proper facilities for keeping their bodies clean is a disgrace to the city and to the civilization of the nineteenth century." The Commission favors as a beginning the building of a municipal bath providing every kind of bath at the cheapest rates.

The Commission makes twenty-one specific recommendations, and embodies them in bills for presentation to the Legislature. The first gives the Board of Health authority to tear down buildings which are unfit for occupation and to compensate the owners. Another relates to the construction of tenement-houses in the future and provides for more light and air and diminished danger from fire. No tenement- or lodging-house shall occupy more than 70 per cent. of an interior city lot, or 90 per cent. of a corner lot, and each room must have a separate window opening to the outer air. Another bill forbids the use of wall-paper in any tenement-house, the better class of apartment-houses being excepted. Another bill provides for the construction of additional public parks, and another, that no school building shall be hereafter

erected without playgrounds, and that as rapidly as possible playgrounds be attached to the schools now existing. Another bill makes it mandatory upon the Board of Health to prevent over-crowding by requiring at least 600 cubic feet of air to each occupant of a tenement-house. Among other recommendations made are those for rapid transit facilities, more lavatories and drinking fountains, more electric lights and more smooth pavements. In conclusion, the Commission recommends the abolition of the present Tenement-House Board, which has not been found to accomplish the ends desired in its establishment, and that in its place another statutory commission upon the subject be created by the Legislature every five years.

## A CHAIR OF ANATOMY, PHYSIOLOGY AND HYGIENE AT WEST POINT.

WE have before us the annual report of the Board of Visitors to the Military Academy at West Point for the year 1894, and find therein that the sub-committee on Hygiene and Athletics, of which Dr. W. W. Keen, of Philadelphia, was chairman, strongly recommends the establishment at the Academy of a separate chair, to be filled by the Senior Surgeon of the post, for the instruction of the cadets in anatomy, physiology, hygiene and first aid to the injured. The reasons given in the report for the establishment of such a chair seem to us cogent, and in fact are such as would naturally present themselves to any one giving careful consideration to the subject — certainly to any one having had a medical training. Such a chair has already been established at the Annapolis Naval Academy, and is filled by a surgeon. The entire instruction in these important subjects at West Point is limited at present, it appears, to six advanced lessons (with five review), together with incidental allusions to various sanitary matters by the professors of chemistry and engineering; to this meagre provision is to be added one lecture by one of the medical officers on first-aid to the wounded.

That the sanitation of armies during war is not merely a medical question; that disease kills and disables a much greater number of men in an army than the weapons of the enemy; that many a valuable life has been lost, in the absence of medical officers, from want of knowledge of first-aid — these are propositions which we suppose few will dispute. If they are granted, the natural conclusion follows. The difficulty at West Point, of course, is that the time of the cadets is already fully occupied. Increased instruction could only be added in case that given in some other subjects should be curtailed. The Committee thinks that the subjects indicated are of more importance to those concerned than mineralogy and geology, and that time might be taken from these latter subjects so that more could be given to the former. This may be regarded as a matter of administrative detail, but the general position taken by the Visiting Committee seems to us a sound one.

The report commends most highly the general sanitary conditions prevailing at West Point, and remarks on the extremely favorable location of the post.

It appears that nearly one-fifth of the cadets require the aid of glasses, and suggestions are made to relieve as far as possible the continued eye strain incurred in reading, writing and drawing. A considerable proportion of the cadets, after leaving the Academy and giving up the incessant near use of the eyes, are able to dispense with their glasses.

Athletic sports and games are recognized by the superintendent as conducive to scholarship and discipline, and the hope is expressed that such pastimes may be encouraged to the [illegible]st, both for recreation and health.

In another part of this interesting report we find an urgent recommendation that increased attention be given to the study of English. Of a grand total of 7,837½ hours of study and recitation in the four years at West Point, over 2,000 hours are given to the mathematical branches, over 1,000 hours each to two other modern languages and to modern physics, 227½ hours to law, 565½ hours to chemistry, mineralogy and geology, and only 294 hours to English! Every officer, the report justly remarks, should know how to use the English language accurately and tersely.

## SANITARY CLIMATOLOGY.

THE general interest manifested in the subject of climate and its influence on health and disease has determined the Secretary of Agriculture, through the medium of the Weather Bureau, to undertake the systematic investigation of the subject.

It is hoped to make the proposed investigation of especial interest and value to the medical and sanitary professions, and to the large number of persons who seek, by visitation of health resorts and change of climate, either to restore health or prolong lives incurably affected or to ward off threatened disease.

The Bureau suggests that, "the study of the climates of the country in connection with the indigenous diseases should be of material service to every community, in showing to what degree local climatic peculiarities may favor or combat the development of the different diseases, and by suggesting, in many instances, supplementary sanitary precautions; also by indicating to what parts of the country invalids and health seekers may be sent to find climatic surroundings best adapted to the alleviation or cure of their particular cases."

The hearty co-operation of the various boards of health, public sanitary authorities, sanitary associations and societies, and of physicians who may feel an interest in the work, is asked to achieve and perfect the aims of this investigation.

No compensation can be offered for this co-operation other than to send, free of cost, the publications of the Bureau bearing upon climatology and its relation to health and disease to all those who assist in the work.

Co-operation will consist in sending to the Bureau reports of vital statistics from the various localities. That these reports may be of value, it is requested that they should be accurate and complete, and be rendered promptly and regularly. Blank forms of reports have been prepared so as to occasion as little trouble and labor as possible on the part of the reporter, and will be furnished by the Bureau on application.

It is hoped to publish soon a periodical devoted to climatology and its relations to health and disease. The publication will probably resemble in size and general appearance the present Monthly Weather Review. More detailed information will be furnished on application to the Chief of the Weather Bureau.

## MEDICAL NOTES.

The Cleveland Medical Society.— Dr. William E. Wirt has been elected president of the Medical Society of Cleveland, Ohio.

Johns Hopkins University keeps what McGill University Desires.— Prof. William Osler of Johns Hopkins University, will not exchange his present sphere of usefulness for one in Montreal.

College of Physicians of Philadelphia. — The annual election of the College of Physicians of Philadelphia was held January 2, 1895. Prof. J. M. DaCosta was elected President, and Prof. John Ashhurst Vice-President, for the ensuing year.

The Slaughter of the Innocents in London. — It is stated on good authority that a thousand infants perish in London each year, from suffocation due to being overlain by their parents in bed. On December 27, 1894, five inquests on the bodies of children who had died from this cause were held in London by one physician.

Professor Wölfler called to Prague.— It is probable that the chair of surgery at Prague, rendered vacant by Professor Gusrenbauer's call to Vienna, will be filled by Professor Wölfler, now of Gratz. Professor v. Ritter v. Hacker, docent at the University of Vienna, and a former assistant of Billroth's will be offered the chair at Gratz.

The Sixty-third Annual Meeting of the British Medical Association will be held in London on Tuesday, Wednesday, Thursday and Friday, July 30, 31, August 1 and 2, 1895. President, E. Long Fox, M.D., Oxon., F.R.C.P., Consulting Physician to the Bristol Royal Infirmary, Eng. President-Elect, Sir J. Russell Reynolds, M.D., Bart., F.R.C.P., F.R.S., President of the Royal College of Physicians.

The Sheppard Asylum. — The third annual report of the Sheppard Asylum, a hospital for mental diseases at Baltimore, Md., is at hand. The photographs with which the pamphlet is illustrated show the buildings and grounds of the institution to be exceptionally attractive from an external point of view, and the interiors also appear to be well arranged and pleasantly furnished.

Typhoid Fever and Oyster Eating.— According to the *British Medical Journal*, numerous cases of typhoid fever probably due to oyster eating have recently occurred in London. No complete demonstration, however, such as was made in this country in the case of the epidemic at Wesleyan University, has so far been made in the London cases, although strong probability has been established that oysters were in some cases the cause of contagion.

The Transmission of Tuberculosis by a Brass Horn. — Dr. Addison S. Thayer, in the *Journal of Medicine and Science*, reports the cases of three young men whose family history was good and who were themselves physically sound, who became infected with tuberculosis by using, as members of a brass band, a second-hand horn hired from a dealer. The possibility of tubercle bacilli being deposited in the convolutions of a horn, to the danger of subsequent players cannot be denied. The three users of the horn in question were the only members of the band who did use it. Two of them are now in Colorado and one in Southern Pines under climatic treatment for tuberculosis. To make the chain of evidence complete it is only necessary to take the horn to pieces and find tubercle bacilli in the dried spittle in its convolutions and joints.

The Treatment of Cholera by Intravenous Infusions of Salt Solution. — In Kronstadt between June 8 and July 21, 1894, 218 cases of Cholera were treated (J. Hazen Torn, *St. Petersburger Med. Woch.*, 49; from *Wratsch*, No. 34). Of 42 cases treated before June 23d, 27 died. On June 23d the treatment by intravenous infusion of salt solution was begun; 193 infusions were performed upon 124 cases. The immediate effect, as is usually the case, did not last. Of the 124 cases treated by infusion, 67 recovered, and 57 died. Of the 67 who recovered, 49 received one infusion, 16 two, and two received three infusions. Of the 57 who died, 22 received one, 22 two, 11 three, and two were given four infusions. Of the 124 cases treated by infusion, there were only 10 which did not belong to the severest type. Leaving out these 10 cases, we have 114 cases of cholera *gravis* with 57 recoveries and 57 deaths — a mortality of 50 per cent. Under the treatment by infusion of normal salt solution, then, the mortality is lowered to 50 per cent. Under the usual methods of treatment the mortality in these cases amounts to 75 per cent.

### BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — During the week ending at noon, January 16, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 82, scarlet fever 72, measles 56, typhoid fever 5. During the week ending at noon, January 23, 1895, the following cases were reported: diphtheria 70, scarlet fever 47, measles 75, typhoid fever 7.

THE FIRST ANNUAL REPORT OF THE MASSACHUSETTS BOARD OF REGISTRATION IN MEDICINE. — The first annual report of the Board of Registration in Medicine, has just been presented at the State House. The whole number of applications of all kinds received up to January 1st has been 4,390. The whole number of certificates issued has been 3,017. Of these, 2,817 have been issued to graduates and 200 have been issued to practitioners of three years' standing; 294 applications have been rejected, leaving some to be accounted for. A large number of these are simply awaiting engrossment, and certificates will soon be issued. Every application received has been carefully investigated and none has been rejected unless passed upon by the full board. A number of those recently received are now being looked up, and some among them no doubt will be found which should not be accepted. "Polk's Medical and Surgical Register" for the year 1893 gives the total number of practitioners 4,012, classified as follows: regulars 2,646, homeopathics 687, eclectics 221, not belonging to the foregoing classes 458. There are now four medical schools in this State which confer degrees in medicine. The receipts and disbursements of the board have been as follows: Up to January 1, 1895, the receipts for fees and paid to the treasurer have been $3,500. The disbursements have amounted to $2,462.08.

POISONING BY WATER-GAS. — Cases of poisoning by illuminating-gas of more or less severity have been rather frequent in Boston this winter. People should not forget that water-gas is more poisonous and has less odor than coal gas, that all gas furnished in this neighborhood now is water-gas, and that especial precautions should be taken in consequence.

THE MEDICAL SCHOOL OF MAINE. — The Medical School of Maine is said to be in prospect of an income of $8,000 a year from invested funds. For some reason the bequest has not as yet become available to the school.

THE ANNUAL REPORT OF THE RHODE ISLAND HOSPITAL. — During the year ending September 30, 1894, 1,730 patients were admitted; 8,163 cases were treated in the out-patient department; 270 surgical operations were performed, with 9 deaths; and 114 gynecological operations, also with 9 deaths. Sixteen autopsies were performed at the hospital during the year. Bequests amounting to $27,000 were received during the year. The deficiency account of the hospital stands at $18,309.91, which represents the excess over income of expenditures not covered by the subscriptions of guarantors since September 30, 1880. The amount reported last year was $18,341.03.

### NEW YORK.

CORPORAL PUNISHMENT FOR CRIME. — At a meeting of the Section on Public Health of the New York Academy of Medicine held January 9th, Dr. Andrew J. Currier read a paper on "Corporal Punishment for Certain Forms of Crime," in which he advocated the whipping-post, especially for wife-beaters. Mr. Elbridge T. Gerry, President of the Society for the Prevention of Cruelty to Children, who took part in the discussion of this paper, thought that flogging should also be used in the case of men convicted of assaulting little girls, and read the draft of a bill which he had prepared for presentation to the Legislature. This bill provides that any person who is convicted of a felony which involves injury to the person of the victim may, in the discretion of the court, be sentenced to not only the penalties provided now by law, but also to be flogged. The number of strokes, which are to be administered on the bare back with a whip or lash, is not to exceed forty, and such punishments are always to be given in the presence of a physician.

DR. BENEDICT APPOINTED CHIEF OF THE BUREAU OF CONTAGIOUS DISEASES. — At the last regular meeting of the Board of Health Dr. C. S. Benedict was appointed successor to Dr. A. H. Doty as Chief of the Bureau of Contagious Diseases, and Dr. Alonzo Blanvelt was made assistant to Dr. Benedict.

## Miscellany.

### THE PRIORITY OF THE DISCOVERY OF ANTITOXIN.

PROF. JAIME FERRAN, of Barcelona, has called the attention of the editors of the *Deutsche med. Wochenschr.* to a paper by him entitled "Nota sobre la vacunacion contra el envenenamiento difterico agudo experimental," bearing date April, 1890, in which a safe and practical method of immunizing animals against fatal doses of the diphtheria poison successfully employed by him is described. On the basis of this publication, which appeared eight months before Prof. Karl Fraenkel's communication on the same subject, Dr. Ferran claims the priority of the discovery. The Spanish bacteriologist's claim, together with the *pièces justificatives*, having been submitted to Prof. Karl Fraenkel, has been frankly acknowledged by him to be well founded. He says (in a letter published in the *Deutsche med. Wochenschr.* of December 27th) that after reading Dr. Ferran's paper he has been able to convince himself that the Spanish worker had in fact, in April, 1890, reported the result of prolonged experiments on the immunization of guinea-pigs against infection with diphtheria bacilli, adding, "there can therefore be no doubt that in this question decisive priority belongs to him."

Prof. V. Babes, of Buda-Pesth, also lodges a claim on his own behalf. He points out, in the same number of the *Deutsche med. Wochenschr.*, that whereas the first communication by Drs. Behring and Kitasato on the immunizing power of the blood serum of artificially immunized animals in the case of tetanus, was published in 1890 in the *Deutsche med. Wochenschr.*, No. 49, 1890, he, in co-operation with Dr. Lepp, had established the same principle as regards "a not less important infective disease" (hydrophobia) in 1889, in a paper published in the *Annales de l'Institut Pasteur*, July, 1889. Professor Babes, however, admits that to Behring belongs the credit of applying the principle to diphtheria. All he claims for himself

is that he took a definite part in laying the foundation-stone of the great and solid structure which Behring and his fellow-workers have raised.

## THE TREATMENT OF INOPERABLE MALIGNANT TUMORS WITH ERYSIPELAS AND PRODIGIOSUS TOXINS.

IN an article on this subject in the *Medical Record* for January 19th, Dr. W. B. Coley gives the following summary of his results:

Up to May 31, 1894, he had treated with mixed toxins twenty-five cases of inoperable sarcoma, eight of inoperable carcinoma, and three of sarcoma or carcinoma. In carcinoma he had noted marked improvement in a number of cases, but no cures. They were all very advanced recurrent tumors. In sarcoma he stated that there were six cases in which he considered there was a reasonable hope of permanent cure. Six months have passed, and none have shown any recurrence. Of two others which were merely mentioned among the tabulated cases as improving, one has gone on to entire disappearance of the very large tumor and promises to be a cure, and the other, a six-times-recurrent sarcoma of hand, is in perfect health at present, nearly two years after the beginning of the treatment. Since May 31, 1894, he has treated twenty-four cases of malignant tumors, all inoperable and mostly recurrent, with the mixed toxins. Of these cases thirteen were sarcoma and eleven carcinoma. In many cases of carcinoma the injections had an undoubted retarding influence, and in some the improvement was extraordinary, but in none did the tumor entirely disappear. In the cases of sarcoma the effect was far more marked; and although in a number of them the disease was so far advanced that there could be no possible hope of recovery, still the powerful controlling influence of the toxins was demonstrated. In three of the thirteen cases the sarcomata have entirely disappeared, and although no great length of time has elapsed the results in his older cases make it improbable that relapse will occur. Of his total of thirty-eight cases of inoperable sarcoma, therefore, nine promise to be permanently successful.

## Correspondence.

### MICRO-PHOTOGRAPHS.

ROXBURY, January 18, 1895.

MR. EDITOR: I condole with you on your ignorance, as pointed out by Dr. Mercer, of Syracuse (JOURNAL, January 17, 1895, p. 71), in your use of the word "micro-photograph" to denote what he calls a "photo-micrograph," which is, as he defines it, "a macroscopic photograph of a microscopic object." Dr. Mercer quotes Maddox and Woodward as authority for his use of the word; he might also have added Sternberg. He does not seem to be aware that you have on your side Robert Koch, Fraenkel and Pfeiffer, and all other German and Continental authorities. Possibly you may have had these stupid foreigners in mind when you perpetrated the blunder so kindly corrected by Dr. Mercer. Perhaps the bias of a foreign education may have disqualified you in some measure for the "correct" use of your mother tongue. Maybe you know too much Greek to be willing to use such a curiously constructed word as "photo-micrograph." If so, I am with you.

Sympathetically yours, "AUSLÄNDER."

### METEOROLOGICAL RECORD,

For the week ending January 12th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer. Daily mean. | Thermometer. Daily mean. | Thermometer. Maximum. | Thermometer. Minimum. | Relative humidity. 8.00 A. M. | Relative humidity. 8.00 P. M. | Relative humidity. Deaths reported 3,013: under five years of age 993; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 331, acute lung diseases 640, consumption 317, diphtheria and croup 177, scarlet fever 56, typhoid fever 34, whooping-cough 18, cerebro-spinal meningitis 16, malarial fever 7, measles 6, small-pox (New York) 1.

From whooping-cough New York 10, Brooklyn 5, Boston 3, Haverhill 1. From cerebro-spinal meningitis New York 8, Worcester 3, Chelsea 2, Boston, Lowell and Hyde Park 1 each. From malarial fever Brooklyn 5, Cleveland and Everett 1 each. From measles New York 3, Brooklyn, Boston and Providence 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530, for the week ending January 5th, the death-rate was 18.9. Deaths reported 3,844:

measles 125, diphtheria 87, whooping-cough 63, diarrhea 45, fever 41, scarlet fever 35, small-pox (Birmingham 2, Liverpool 1) 3.

The death-rates ranged from 14 1 in Cardiff to 25.0 in Gateshead; Birmingham 20.7, Bradford 15.2, Burnley 19.4, Croydon 18.1, Hull 15.6, Leeds 24.1, Leicester 17.2, Liverpool 24.2, London 17.4, Manchester 23.4, Newcastle-on-Tyne 17.6, Nottingham 15.9, Sheffield 19.9, Swansea 23.7, West Ham 17.1.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 12, 1895, TO JANUARY 18, 1895.

COL. JOSEPH R. SMITH, assistant surgeon-general, will be relieved from duty as medical director, Department of the East, to take effect about February 5, 1895, and will proceed to his home where he is authorized to await retirement.

---

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 19, 1895.

JAS. R. WAGGENER, surgeon, placed on waiting orders.

L. W. CURTIS, passed assistant surgeon, detached from Naval Hospital, Chelsea, Mass., and placed on waiting orders.

L. H. STONE, passed assistant surgeon, ordered to the U. S. S. "Alliance," January 22d.

J. G. AYERS, passed assistant surgeon, ordered to the U. S. S. "Olympia."

M. R. PIGOTT, passed assistant surgeon, ordered to the U. S. S. "Olympia."

---

## OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDING JANUARY 15, 1895.

CARTER, H. R., surgeon. To assume temporary command of Cape Charles Quarantine. January 7, 1895. Relieved from such duty. January 14, 1895.

PERRY, T. B., passed assistant surgeon. To proceed to Delaware Breakwater Quarantine Station for temporary duty and to rejoin station (Cape Charles Quarantine) upon completion of same. January 14, 1895.

WERTENBAKER, P., assistant surgeon. Granted leave of absence for seven days. January 3, 1895.

---

## HARVARD MEDICAL SCHOOL.

### EVENING LECTURES.

The next lecture will be given on Thursday evening, January 31st, at 8 o'clock, by Dr. E. Cowles. Subject, "The Relation of Insanity to Neurasthenia." Physicians are cordially invited.

---

## SOCIETY NOTICES.

THE WARREN CLUB. – A regular meeting of the Club will be held at 14 Marlborough Street, on Tuesday evening, February 5th, at 8 o'clock.

Dr. Homer Gage: "Movable Kidney."

W. E. PAUL, M.D., *Secretary*.

NORFOLK DISTRICT MEDICAL SOCIETY. – The Fellows of the Norfolk District Medical Society resident in Jamaica Plain, will entertain the Society at Arcanum Hall, 658 Centre Street, on Tuesday, January 29th, at 8 P. M.

Communications: "The Theories of Immunity and the Methods of Preparation Involved in the Antitoxin of Diphtheria," H. C. Ernst, M.D. "Clinical Results of the Use of Antitoxin," C. F. Withington, M.D. "A Severe Case in Private Practice Treated with the Antitoxin," O. F. Rogers, M.D.

Collation at 9.30.

The meeting will be called to order promptly at 8 o'clock, and members are requested to make special effort to be present at that time.

Attendants at the hall will take charge of horses, stable them and return them at close of the meeting, free of charge.

Centre Street electric cars pass the hall every ten minutes.

J. C. D. PIGEON, M.D., *Secretary*.

---

## BOOKS AND PAMPHLETS RECEIVED.

Notes on a Few Clinical Experiences of Inherited Syphilis. Seborrhea. By Burnside Foster, M.D., St. Paul. Reprints. 1894.

Report of the Surgeon-General, U. S. Navy, Chief of the Bureau of Medicine and Surgery to the Secretary of the Navy. Washington. 1894.

Fourth Report of the State Board of Health of Colorado, Including the Reports for the years 1892, 1893 and 1894. Denver: Published by the State. 1894.

Transactions of the American Otological Society, Twenty-seventh Annual Meeting, Arlington House, Washington, D. C., May 29, 1894. Vol. VI. Part 1.

Four Months in New Hampshire, a Story of Love and Dumb Animals. Written for, and revised, copyrighted and published by the American Humane Education Society. 1894.

The Dynamics of Life, an Address delivered before the Medical Society of Manchester, October 3, 1894. By W. R. Gowers, M.D., F.R.S. Philadelphia: P. Blakiston, Son & Co. 1894.

United States Bureau of Education, Circular of Information, No. 1, 1894. No. 18. History of Higher Education in Rhode Island. By William Howe Tolman, Ph.D. Washington. 1894.

Twenty-sixth Annual Report Relating to the Registry and Return of Births, Marriages and Deaths in Michigan for the year 1892. By the Secretary of State of the State of Michigan. Lansing. 1894.

Statistiques et Observations de Chirurgie Hospitalière. Par la Dr. Polaillon, Chirurgien de l'Hôtel Dieu, Professeur agrégé à la Faculté de médecine de Paris; Membre de l'Academie de médecine. Paris: Libraire Octave Doin, Editeur. 1894.

Travaux d'Electrothérapie Gynécologique, Archives Semestrielles d'électrothérapie gynécologique Fondées et Publiées. Par le Dr. G. Apostoli, Vice-Président de la Société Française d'électrothérapie. Paris: Société d'Éditions Scientifiques. 1894.

Annual Report of the Medical Officer of Health of the Vestry of St. George the Martyr, Southwark. By F. J. Waldo, Diplomate in Public Health of the Royal College of Physicians and Surgeons (England), M.R.C.S. (England), etc. Southwark. 1894.

A System of Legal Medicine. By Allan McLane Hamilton, M.D., Consulting Physician to the Insane Asylums of New York City, etc., and Lawrence Godkin, Esq., of the New York Bar, and others. Illustrated. Vol. II. New York: E. B. Treat. 1894.

Higher Medical Education the True Interest of the Public and of the Profession. Two addresses delivered before the Medical Department of the University of Pennsylvania on October 1, 1877, and October 2, 1893. By William Pepper, M.D., LL.D. Philadelphia: J. B. Lippincott Co. 1894.

Castration for Hypertrophied Prostate. Removal of the Head of the Femur from the Lesser Sciatic Notch. The Removal, by Trephine, of Fluid as the Result of Acute Cerebral Meningitis, with Report of a Case. Fifty Cases of Rectal Surgery. By B. Merrill Ricketts, M.D., Cincinnati, O. Reprints. 1894.

Manual of Practical Morbid Anatomy, being a Handbook for the Post-Mortem Room. By H. D. Rolleston, M.A., M.D., F.R.C.P., Fellow of St. John's College, Cambridge; Assistant Physician and Lecturer on Pathology at St. George's Hospital, and A. A. Kanthack, M.D., M.R.C.P., Lecturer on Pathology at St. Bartholomew's Hospital. Cambridge: University Press. 1894.

Diseases of the Ear; a Textbook for Practitioners and Students of Medicine. By Edward Bradford Dench, Ph.B., M.D., Professor of Diseases of the Ear in the Bellevue Hospital Medical College; Aural Surgeon, New York Eye and Ear Infirmary; Fellow of the American Otological Society; of the New York Academy of Medicine, etc. With colored plates and illustrations. New York: D. Appleton & Co. 1894.

Textbook of Hygiene; a Comprehensive Treatise on the Principles and Practice of Preventive Medicine from an American Standpoint. By George H. Rohé, M.D., Professor of Therapeutics, Hygiene and Mental Diseases in the College of Physicians and Surgeons, Baltimore. Third edition, thoroughly revised and largely re-written, with many illustrations and valuable tables. Philadelphia: The F. A. Davis Co. 1894.

The Principles of Surgery and Surgical Pathology, General Rules Governing Operations and the Application of Dressings. By Dr. Hermann Tillmanns, Professor in the University of Leipzig. Translated from the third German edition by John Rogers, M.D., New York, and Benjamin Tilton, M.D., New York. Edited by Lewis A. Stimson, M.D., Professor of Surgery in University of the City of New York, Medical Department. With 441 illustrations. New York: D. Appleton & Co. 1894.

Sexual Neurasthenia, Its Hygiene, Causes, Symptoms and Treatment, with a Chapter on Diet for the Nervous. By George M. Beard, A.M., M.D., formerly Lecturer on Nervous Diseases in the University of the City of New York; Fellow of the New York Academy of Medicine; Member of the American Neurological Association, etc. Edited with notes and additions by A. D. Rockwell, A.M., M.D., formerly Professor of Electro-Therapeutics in the New York Post-Graduate Medical School and Hospital; Member of the New York Neurological Society, etc. New York: E. B. Treat. 1895.

## HINTS CONCERNING THE PERFORMANCE OF THE OPERATION FOR THE EXTRACTION OF SENILE CATARACT, BEING A RECORD OF PERSONAL EXPERIENCE.

BY HASKET DERBY, M.D., BOSTON.

A RECENT excellent and instructive article entitled "Practical Advice to Young Ophthalmic Surgeons in regard to the Operation for Cataract," by Dr. Hermann Pagenstecher,[1] contains so much valuable information in regard to the results of his own experience, that I was at first tempted to simply offer a translation of the whole for the columns of the JOURNAL. But subsequent reflection has convinced me that, as the aim of the author was to express his personal views and predilections, it might be well for a surgeon living in another country, dealing moreover with people varying from the Germans in habits, constitution and temperament, to state the conclusions at which he himself had arrived after many years of practice.

I have kept full notes of all the extractions of senile cataract made by myself, both at the Massachusetts Eye Infirmary, the Carney Hospital and in private practice since the year 1865. It is not my intention here to analyze them numerically or to give tables of results. My present purpose is simply to present to those now coming on the stage a *résumé* of the experience I have gained from the careful study of my different operations, the consequences of the various modifications in technique and after-treatment I have successively practised, and the subsequent history of the patients, followed up in many instances for a number of years afterwards. I by no means lay claim to wisdom superior to that of my colleagues, or maintain that my own conclusions are more apt to be correct than the ones formed by those who may differ from me. But thirty years of practical experience have instilled in me some positive convictions, and I give them for what they are worth.

It is my intention to discuss the best manner of restoring useful vision to the subjects of senile cataract. Confining then our study to this class of cases, I start with two axioms. The first, that no operation is to be done on one eye as long as the lens of the other is wholly transparent; the second, that, save in most exceptional cases, entire maturity is to be awaited.

In the great majority of cases both crystalline lenses are found to be affected, though rarely to the same extent. But this rule is not universal. One of the first cases of cataract in which I was consulted was that of a well-known surgeon of this city, then sixty-five years of age. One of his eyes was the seat of a mature, uncomplicated senile cataract, while the other was entirely free from disease. He retained the sight of this eye unimpaired and practised his profession to the day of his death, some ten years later. The relatively slight advantage this gentleman would have gained from the enlargement of his field of vision after a successful operation might have been more than met by the impression made on his general health through the prolonged confinement and interruption in his usual habits which his convalescence would have entailed.

In regard to maturity much is said at the present day concerning the possibility of the extraction of the lens, particularly in the case of aged people, in almost any stage of opacity; nay, the removal of the transparent crystalline is seriously proposed as a remedy for extreme myopia. My own experience leads me to believe that the absence of perfect ripeness invariably diminishes the chances of success, in many cases complicates convalescence, and always renders the satisfactory performance of the operation more difficult. Of course there are occasions on which, of two evils, the lesser must be preferred, and times when it is better to encounter the risk of removing a cataract that is not wholly ripe than to leave an aged patient, who has wholly lost the power of reading and writing, to the depressing effect of forced idleness. It was but last summer that I operated on one eye of a gentleman, eighty-five years of age, in whom cataract had for three years past been gradually developing. He had slowly reached the point of being unable to go abroad without attendance, and all power of reading had been lost. Yet his vision in the worst eye was fully one-tenth, and a view of the fundus could still be obtained through the partially opaque lens. He was a man of acute intellect and active habits, his health was now beginning to suffer from lack of exercise, and his morale was much impaired. In this case, if any, an operation on an immature cataract was justifiable, it being reasonable to suppose that the yet transparent corticalis was closely connected with the large nucleus and would escape with it. On performing the extraction this certainly seemed to happen, an apparently clear pupil being left and vision being good, but on opening the eye eight days later I found the entire pupillary area filled with opaque cortical, and vision reduced to perception of light. His convalescence was a lengthy one, but absorption finally occurred without inflammation; no secondary operation had to be performed, and he now has a vision of five-tenths and has resumed the direction of his business affairs.

The matter of prognosis is one on which the surgeon is invariably approached, one of the first questions put by the patient or his friends being as to the chances of success. It may safely be stated that, in an uncomplicated case of mature senile cataract, occurring in a reasonably healthy patient under or not much past eighty-five, where the cornea is fairly large, the pupil readily dilatable, and the conjunctiva as well as the lachrymal apparatus free from disease, the chances of regaining useful vision are at least eighty-five per cent., while those of total loss of the eye may be estimated at two per cent. Where the above conditions are fulfilled, this certainly agrees with my own experience. We operate, however, in many instances where they are not, and no law as to the effect of complications on ultimate success can be formulated.

As regards the place of performance of the operation I see no reason for departing from the principle I have always laid down, that it should be away from home, preferably in a private hospital or else in one of the private rooms in a public one. Care at the hands of attendants and nurses familiar with such operations will thus be secured, while the advantage of a place constructed and arranged for this special purpose must be greater than that afforded by the ordinary private house. There remains, moreover, the fact that the patient is removed from the occurrences of home-life, is not annoyed by officious relatives or well-meaning visitors, and escapes possible household troubles and cares. I always prefer that the patient should pass the preceding night in the room in which

[1] Monatsbl. f. Augenhlkde., November, 1894.

the operation is to be performed, that he may gain a knowledge of his surroundings before the application of the bandage.

*Preparation for the Operation.*— The patient should take a warm bath the evening before. An hour or so before operating the parts about the eye and the outer surface of the lids should be thoroughly washed with soap and water. I then saturate a thick compress with a solution of corrosive sublimate (1–5,000), and suffer it to remain on the closed eye till the cocaine is applied. After a drop of a two-per-cent. solution of cocaine has been instilled into the eye and has exerted its anesthetic effect, it is my practice to wash out the conjunctival sac thoroughly with the above sublimate solution. The slight irritation caused, in many cases, by the application of a solution of this strength to an eye that has not been cocainized seems to me undesirable.

The instruments, with the exception of the fixation forceps the rubber tips of which would thereby be softened, are dipped in boiling water, carefully dried with a piece of carbolized linen which is taken from the sterilizer, and laid on a glass-topped table that has been washed down with the same sublimate solution. The fixation forceps are to be dipped in absolute alcohol. There is no objection to immersing all the instruments in a tray filled with this liquid, but I do not believe it to be necessary. The hands of the surgeon, having been thoroughly scrubbed with sublimate soap, should afterwards be dipped in the sublimate solution. Should there be an assistant, he ought to adopt similar precautions. But I do not find the services of an assistant necessary, and cannot remember having taken one to a cataract operation in private practice for the past twenty years. With the disuse of ether it would seem that all necessity for additional professional help has disappeared, the patient having now full possession of his faculties and being able to help the operator by turning the eye in the desired direction. If the operation be performed in a hospital a trained nurse will, of course, always be present, and can prepare and pass the various applications and dressings, removing the latter from the sterilizer as they are needed.

*Shall Iridectomy be Performed or No?* — This is the burning question of the present day. In favor of leaving the iris intact may be mentioned the lessened operative interference with the eye, there being but one wound to heal instead of two, the cosmetic effect of a round central pupil, and the protection afforded by its spontaneous dilatation and contraction. Against simple extraction are to be alleged the increased difficulty in removing cortical substance that may remain behind from the pupillary area, and the great danger of prolapse of the iris. And, in consideration of this, I see no reason for departing from the belief I have always entertained that the average patient at the hands of the average surgeon stands a better chance of an uncomplicated recovery, and in consequence thereof of attaining useful vision, if iridectomy be performed. It is true that great and practised operators obtain excellent results in the vast majority of cases from simple extraction, and that many of them at this time are inclined to make it the rule, and the combined operation the exception. But even they must accept the fact that no amount of experience in selecting cases, or of manual dexterity in operating, can enable the surgeon to declare that in any given case iris prolapse may not occur. In a series of a hundred attempted simple extractions it will be found that six or eight iridectomies have to be done after the removal of the lens, on account of the difficulty experienced in maintaining reposition of the iris. And the performance of iridectomy at this stage is always a most delicate and difficult proceeding. And in from eight to ten other cases, out of the same hundred, iris prolapse takes place under the bandage, owing to some sudden motion of the patient or without assignable cause.

If this is the experience of the older surgeons, what might be that of the beginner? I maintain therefore that the young practitioner will do well to combine iridectomy with extraction.

After the instillation of cocaine, a two-per-cent. solution of which may be dropped in the eye at least twice before the operation, at three-minute intervals, the first step in the operation is the introduction of the spring speculum. That made by Weiss, of London, I consider the best. It is light and manageable, adapts itself to the face, has not too strong a spring, and can readily be withdrawn.

The cut being made upwards fixation is applied directly below the cornea. For this purpose I have discarded the ordinary toothed forceps, and employ the rubber-tipped ones used to hold the eyeball during the operation of tattooing the cornea. It is true that the hold we thus obtain is somewhat less firm, but it generally suffices, and unless the conjunctiva is very friable it is rarely wounded.

The cut is made at the sclero-corneal junction, and should extend over one-third of the periphery of the cornea, being crescentic in shape. Pagenstecher, whose view as to the cut I have here reproduced, advocates the formation of a conjunctival flap, from which I wholly dissent. He has already dwelt on the advantage of eliminating a second wound in the shape of the iridectomy, and yet now advises the infliction of one much larger and more external, involving a relatively large healing area. It has ever been my practice, on completing the corneal cut, to turn the blade of the knife forward and cut out as rapidly as possible, fixation being at once and finally desisted from.

Before proceeding to the iridectomy cocaine should once more be instilled. The patient then being requested to look down, and at the same time warned as to the possibility of slight momentary pain, as well as the necessity of avoiding any sudden movement at this critical moment, the iris is grasped at its pupillary edge and a small coloboma formed. In many cases no special pain is felt, the senile iris appearing to lose a portion of its sensitiveness. Should any iris tissue be caught in the corners of the corneal wound, it is well to free and replace it with the small flat rubber spatula before opening the capsule.

The speculum is now carefully withdrawn. If, in spite of the styptic action of the cocaine, any hemorrhage should now be present, it may be controlled by allowing the patient to gently close the eye, and by applying externally a wad of sterilized lint dipped in an ice-cold solution of the sublimate indicated above. From this time forth the operator himself raises the upper lid with the forefinger of the left hand, when it is desired to expose the eye. He is thus in a position to allow the eye to close at once, should a sudden loss of vitreous occur, and to avoid the aggravation of this accident which the removal of a speculum might

entail. The capsule is to be thoroughly incised in different directions with the cystitome. I see no advantage in the peripheric opening advised by some writers.

*Removal of the Lens.* — My own practice has always been to bring this about by pressure made at the base of the cornea, through the lower lid, the pressure being exerted by means of the back of the rubber scoop. After the escape of the lens any remaining fragments of cortical may be collected in the centre of the pupil, by judicious rubbing through the closed upper lid, and then chased to and made to escape from the wound by stroking the eyeball upwards through the lower lid, the patient the while looking a little down. If, as is often the case, the fragments are arrested at the wound by the coaptation of its edges, these may be held apart by means of the Daviel spoon, used simply to encourage separation and not introduced into the anterior chamber. Even here the services of an assistant are unnecessary. The surgeon holds the upper lid against the edge of the orbit by means of the little finger of his left hand, manœuvres the spoon between the thumb and forefinger of the same hand, and uses his right to propel the fragments of cortical substance towards the wound and out of the eye. The irrigation of the anterior chamber for cleansing purposes is a difficult and delicate proceeding, and, although in the hands of experienced operators it may sometimes be productive of good results, it is never to be advised the beginner, who had better run the risk of allowing a small amount of lens matter to absorb than follow a method the results of which are sometimes so harmful.

Should vitreous escape before the lens is removed, and especially if the latter shows a tendency to become dislocated backward or downward, the scoop (preferably that of Bowman) should be at once introduced and the lens extracted. As this is a contingency that may at any time occur, it is well to have the scoop in readiness and thoroughly disinfected before commencing the operation.

After the removal of the lens and the clearing of the pupil, the rubber spatula is to be passed into each corner of the wound, to free any fragment of iris or capsule that may have lodged there. A drop of a one-per-cent. solution of eserine, instilled into the conjunctival sac before closing the eye, tends to withdraw the iris from the wound and thus prevent prolapse. A sterilized bandage is then to be applied.

I always endeavor to operate in the early morning; and it is my custom to visit the patient again late in the afternoon and change the bandage, washing the outside of the eye with sterilized lint dipped in sterilized water, but not separating the lids. This is repeated thereafter once a day until the eighth day, when I make my first examination of the eyeball. It was in 1882 that I first [3] published my reasons for adhering to this plan of non-interference with the eye during the healing process. When students we had all been taught to examine the wound soon after the operation. Donders always did this the same evening. Graefe used to advise that, on the first removal of the bandage, the upper lid be gently raised and a hasty glance taken at the lower part of the cornea by the aid of a single candle. It was only by gradual degrees that I came to postpone the opening of the eye, the interval growing longer and longer, and I ever found that, within certain limits, the more I postponed my first examination the better was the condition of things. Of course, the rule is not invariable; there are cases where the skin will not so long support the irritation of continued pressure and requires earlier exposure to the air. And where pain, swelling, lachrymation and discharge warn us that the normal healing process is not going on, an immediate examination must be made.

In order to secure dilatation of the pupil I frequently wet with the usual solution of atropine the small piece of linen that is placed directly on the eye and serves to prevent fragments of lint from getting in between the lids. This is done daily for several days previous to opening the eye, and is found in the majority of cases to affect the pupil. It is especially desirable to do this in cases where cortical substance is known to have been left behind.

In regard to the claim that, after the operation of extraction, only one eye need be guarded, the lids being lightly closed with plaster; that the patient may be allowed to remain in a light room, and even to use the other eye; it may be replied that undoubtedly some eyes recover under these or even more unfavorable conditions, and that accurate and extended statistics must be substituted for vague assertion before the average surgeon will be justified in so serious a departure from precautions which have stood the test of long experience.

I seldom find it necessary to confine the patient to the bed more than twenty-four hours. On the afternoon of the operation a bed-rest may be used under the shoulders, and a half-sitting posture indulged in, a change always productive of much relief. After dressing the eye the following morning the patient is allowed to leave the bed and occupy an easy chair, wearing a loose wrapper. On the third day the ordinary clothing may be resumed and a walk up and down the entry allowed, an attendant being of course at hand. The mild form of mania that occurs with some old people a few days after the operation is largely due to the combined effect of darkness and solitude. Hence pleasant society is always desirable. A friend or attendant should be in the room most of the time, and the patient conversed with or read to as much as possible. At the hospital where I generally operate we have deep windows with drapery hanging in front of the recess, leaving room for the reader behind the curtain. But in other places a screen may be used, with a light behind it. After the first day or two I do not regard darkness of the chamber as desirable, a moderate degree of light being allowed to enter. Sudden changes of light are to be avoided.

Such an article as the present might be almost indefinitely prolonged. It is a record of personal experience and is to be taken for what it is worth. I have seen flap extraction with the triangular knife, the operation generally practised during my student days, modified later by previous iridectomy, entirely superseded by the method of Graefe, this in its turn reinforced by local anesthesia and asepsis, as well as changed in various details. In the face of such mutations, occurring during the life of a single individual, it is not improbable that we are on the threshold of even greater changes, and that the teachings given in the present article will before long offer a simply historical interest.

[3] Anesthesia and Non-Anesthesia in the Extraction of Cataract.

## APPENDICITIS.[1]

BY GEORGE W. GAY, M.D.,
*Surgeon to the Boston City Hospital.*

MR. PRESIDENT AND GENTLEMAN: — No apology is required for bringing before you for discussion upon this occasion one of the most important surgical affections of the present day. Appendicitis is important by reason of its frequency; by reason of its character, serious in all cases, and fatal in many; and also by reason of the grave difficulties attending its management in numerous instances.

Inflammation of the vermiform appendix varies in degree from a simple catarrhal affection indicated by a slight and transient bellyache; to sudden and complete gangrene of the whole organ attended by symptoms of most profound collapse, which may terminate fatally in twenty-four to forty-eight hours in spite of any and all modes of treatment. In not a few instances the symptoms are so slight, and give so little discomfort, that their true significance is not suspected, until frequent recurrence, or increased severity reveals the real character of the affection.

The chief source of danger from inflammation of the appendix, as you all so well know, is the resulting peritonitis. The danger is usually in direct proportion to the extent of the inflammatory process, general peritonitis being one of the most serious affections with which we have to contend. Not infrequently insidious in its approach, remitting in its progress, devoid of alarming symptoms, the patient is beyond all help before his real condition is apparent to the attendants.

Sudden abdominal pain, aggravated by coughing and tenderness, are the characteristic symptoms of peritonitis, and peritonitis in the male in nine cases out of ten is due to inflammation of the appendix. In the female the Fallopian tubes, ovaries and other pelvic structures require consideration before arriving at a final diagnosis. A painful, tender belly, whether the tenderness be local or general, should always suggest peritonitis to the observer, whatever other symptoms may be present, or absent. Rigidity of the abdominal walls, and fever render the diagnosis more certain. Tenderness or muscular rigidity more marked on the right side of the median line, together with vomiting and tympanites, are additional evidence in favor of appendicitis. Previous attacks also suggest the nature of the affection. In some cases of undoubted inflammation of the appendix, as shown by operation or autopsy, there is no localization of symptoms at any time, so that we are compelled to fall back upon the general statement already made, that peritonitis in the vast majority of instances means appendicitis.

The diagnosis is made almost certain by the presence of a bunch. This is usually situated in the right lower quadrant of the abdomen, but may be located near the liver or even upon the left side, in fact in almost any part of the abdomen. Instead of a bunch there may be marked local resistance on the right side in strong contrast to the elasticity of the opposite side.

Occasionally the tender spot and the tumor may be detected by a rectal or vaginal examination, both of which should always be made. The appendix is at times located deep in the true pelvis alongside the rectum, in which case the characteristic symptoms might not be apparent upon the surface of the abdomen, until late, or even not at all.

Again, a tumor may be obscured by distention, by rigidity of the muscles, or by great resistance to manipulations, so that its absence is of little importance, as regards the diagnosis. It is no unusual event to find large quantities of pus in the peritoneal cavity in the absence of a tumor, and of localized pain and tenderness. Even a tympanitic abdomen may contain a large amount of pus. Persistent pain, tenderness, and muscular tension tell the real condition of things inside. They indicate the presence of peritonitis, and that, as mentioned above, in the vast majority of cases met with in every-day work, means appendicitis, and should be recognized and treated as such.

The diagnosis being reasonably certain we next have to consider the management of the case. About half of the persons afflicted with this disease recover under simple treatment, such as rest, leeches, opiates, fomentations, etc. Of those, who undergo operation, from one-half to three-quarters recover. One of the most difficult questions arising in the treatment of the malady is to decide, what cases require operation, and also, when shall it be done. It is much easier for an experienced surgeon to decide these questions in his own mind at the bedside, than it is to lay down rules for others to follow. In a general way, however, it may be said, that the cases in which the symptoms are sudden, sharp and severe, thereby indicating perforation and gangrene of appendix, demand early and prompt operation, that is, on the second or third, and perhaps upon the first day of the disease. Cases of moderate severity had better be operated upon in three or four days, if there are no marked and sure signs of diminution of the symptoms. But frequent and careful observations are necessary to prevent one from being deceived by latent symptoms. No improvement is reliable until it has lasted for more than twenty-four hours. Too much reliance must not be placed upon the pulse and temperature, as they are often very deceptive in their character.

A patient with this affection is never safe until he can pass wind. I care not how favorable all the other symptoms may be, so long as he cannot get rid of the flatus in the natural way, he is in a condition to give anxiety to his medical attendant. Obstruction of flatus may be due to intestinal paresis, or to mechanical causes. Septic infection often produces paralysis of the intestines, and thereby allows of their great distention. In a fatal case at the Boston City Hospital last winter, Dr. Councilman, the pathologist, found that death was caused by portal thrombosis, that is, thrombosis of one of the mesenteric vessels, which produced paresis of peristalsis. The gravity of distention due to intestinal paralysis cannot be overestimated, as a fatal result is the rule. Rumbling of gas in the bowels is always a welcome sound, and one of the most favorable symptoms in peritonitis is a free escape of flatus.

Light cases of appendicitis require operation when the symptoms of improvement come to a standstill. I cannot agree with those, who say, that every case of appendicitis, however slight, should be operated upon. I still have some respect for the peritoneum. About half of the patients get well without radical measures, and unless time and experience shall prove that these people are pretty sure to have a recurrence, it is difficult to see any good reason for subjecting them all to

[1] Read before the White Mountain Medical Society at Hanover, N. H., July 31, 1894.

operation. I very much doubt if that practice will ever come into general acceptance by the profession.

Cases attended by frequent exacerbations are better treated by abdominal section. I should seldom, if ever, wait longer than the second relapse, before advising operation. Relapses and recurrences indicate a condition of things in and about the appendix which Nature cannot readily repair, and too much risk should not be incurred by waiting. I venture the assertion that more mistakes are made by late than by early interference.

It should be said that this question of operation might be affected by the patient's station in life. It is not as imperative that an early operation should be performed upon a person of means, who can command at any and all times the best professional skill, as it is in the case of one living a long distance from skilful aid, or of a poor man obliged to work for a living, and subject to all the risks and exposure incident to such a life. Moreover, the latter person can ill afford the time and expense for a long convalescence.

A tumor does not necessarily call for an operation. I know of several members of our profession, one of whom is an honored occupant of an important chair in your own medical school, who have recovered from attacks of this disease attended, among other symptoms, with a tumor. The bunch would indicate the site of the incision, rather than the necessity for an operation. In not a few of the worst cases, cases calling most imperatively for an operation, no tumor is present. To give exit to the pus, and to get rid of the source of irritation, is the object of the operation. In some instances there is no suppuration in the bunch. It is solid, and composed of inflammatory products, which do not soften and break down, but are removed by absorption. I would like to remark in passing, that an early appearance of the tumor indicates that the appendix lies close to the abdominal parietes, rather than deep in the iliac fossa, or true pelvis. In one of my cases the bunch made its appearance upon two occasions within twenty-four hours, and at the operation, after her recovery from the second attack, the appendix was found as above indicated.

For recurring appendicitis in which there is a distinct interval between the attacks, I believe most thoroughly in an operation for removal of the offending organ. This method of treatment is reasonably safe, and it is effectual. The risk of future, and perhaps of a fatal attack is thereby removed, and the mental anxiety, which is by no means an insignificant factor in the matter, is relieved. In short, the best of arguments, reason and experience are in favor of the operation, and nothing of importance can be brought against it.

Two attacks of appendicitis, even if slight, and not too far apart, justify an operation for removal. In one of our recent operations during the interval after the second attack in six months, the appendix was distended with a purulent fluid, threatening perforation at any time.

A patient with recurring, or "sleeping," appendicitis is in constant danger of an explosion, which may prove fatal in spite of the most prompt and skilful treatment; hence the very great importance of interfering at the proper time.

By way of summary then, I would say, that an operation is indicated: (1) In very severe cases, and immediately. (2) In moderate cases in three or four days, if the symptoms are not progressing favorably. (3) In slight cases, if they do not get well in a reasonable time, or do not steadily progress toward recovery. (4) In cases attended with frequent exacerbation without any distinct interval. (5) In recurring cases, and, as a rule, in the interval after the second attack. (6) Cases of doubtful diagnosis, in which the symptoms do not subside within a reasonable time, may be subjected to exploratory incision, with the expectation, that more good than harm will be done in the long run. (7) Patients who must live out of reach of competent medical attendance, as well as those in the humbler walks of life, may require operation under circumstances not otherwise advisable.

On the other hand, light cases, and those of moderate severity that show signs of improvement upon the third day, do not require operation during the first attack, providing convalescence is not interrupted or prolonged.

I would not advise operation during profound collapse, as I have never seen a person rally under these circumstances. General peritonitis does not necessarily preclude an operation, yet the prognosis is exceedingly grave in these cases. I have seen only one patient recover after laparotomy performed during a severe general peritonitis. As the result, however, is occasionally successful after operative treatment, as well as under the expectant method, the physician may be left to decide this very evenly balanced question for himself, according to his own notions upon the matter, with the assurance that he will find ample authority for whichever method he may select. My own custom is to recommend operation, if I think the patient's condition will enable him to get through it, and not succumb during its performance. I cannot urge too strongly, that each and every case of appendicitis should be watched very carefully until the fate of the patient is decided. He should be seen at least twice a day; and if the symptoms are very severe, he ought to be visited every four to six hours, if circumstances will permit. I fully appreciate the difficulties of carrying out these suggestions in thinly settled regions in the country, where the physician lives many miles away from his patient. Under these conditions operative measures might be resorted to at an earlier period, rather than run too much risk by waiting for further developments.

Peritonitis, as you know, is in many instances very rapid in its progress, oftentimes invading the serous cavity throughout its entire extent in a few hours. The shock and prostration under these circumstances is most profound, precluding in many cases any operative interference. Hence the importance of close and frequent observation, as well as prompt action, before it is too late to avail ourselves of the natural recuperative powers of the system.

I shall touch upon only a few points as to the manner of doing laparotomy for appendicitis. Two classes of cases are met with in our every-day work.

In the first, the incision leads directly into the abscess cavity, which may be a portion or the whole of the peritoneal space. In the most favorable conditions the disease is limited to a small part of this cavity by a retaining wall of lymph, and an operation is little more than opening a deep abscess. This may be done by the so-called Hilton method, which consists in dividing the tissues down to the transversalis fascia, puncturing the abscess with a blunt instrument, as a

director, and dilating the opening thus made to the desired extent.

In the second class of cases, on opening the peritoneal cavity, the disease is found to be walled off deep in the pelvis, or in a mass of intestines or omentum, and drainage is possible only through the general peritoneum. This is a very undesirable complication to encounter, as pus in the peritoneal cavity is one of the most dangerous conditions attending the affection. The peritoneum is to be protected by carefully packing sterilized gauze all about the abscess, leaving a space in the centre or to the outer side for the exit of the discharges and for drainage. Care is to be taken in the manipulations that the abscess is not prematurely ruptured, thus allowing the pus to escape into the peritoneal cavity among the coils of the intestines before the packing is complete. Everything being in readiness, the retaining wall can usually be broken down easily with the finger, and the examination carried to the desired extent.

The cavity of the peritoneum, or of the abscess, having been opened, several difficulties may now be expected. Naturally the first object to be sought for is the appendix. In the late cases it may have sloughed off, when it will very likely escape in the discharge, together with the little fecal mass so often found in these conditions. Not infrequently, however, it will be so covered over by exudation and adhesions, as to be indistinguishable from the other structures, either by sight or touch. And just here comes up the important question, as to how far the search for the offending member shall be carried. I think that the present concensus of opinion is in favor of doing much less violence to the parts in our endeavors to find and remove the appendix, than formerly. It is no easy matter to detect it, and to dig it out of a mass of adhesions, in which may be omentum, intestines, blood-vessels, etc., all located deep in the pelvis. Nor are such efforts, which are necessarily made in the dark, and largely by the sense of touch, free from danger.

So far as I can judge from the experience of others, as well as of my own, it makes little difference in the immediate result, whether the appendix is removed at the time of the operation or not. Dr. Miles F. Porter, of Fort Wayne, in the *American Journal of Medical Sciences* for December, 1893, gives a table of 448 cases of appendicitis treated in various ways. In 122 instances the appendix was removed at the time of the operation. The recoveries were, in round numbers, 80 per cent. One hundred and fifty-four cases were treated by simple incision and drainage; the results were 81 per cent. of recoveries. This difference is not of sufficient importance in itself to influence the operator's action. If future experience shall prove, as it now bids fair to do, that patients do as well when the appendix is left as they do when it is removed, the labors and anxieties of the operator, as well as the danger to the patient, will be very much diminished. For my own part I do not search half as curiously for this organ, as I formerly did. If it is pretty readily found, an effort is made to remove it; otherwise the case is treated like any deep suppuration.

Another important point requires a moment's notice here, and that is the future condition of the patient. Does removal of the appendix render him any less likely to recurrence? While time and experience will not yet allow us to decide this point too positively, I think that recovery is more sure and speedy, and relapses rather less common in those cases in which the appendix has been removed, either by the surgeon or by natural processes. I have never seen a recurrence after removal of the tube; I have seen two or three relapses under the opposite condition.

According to our present light, however, relapses are not common enough to justify too earnest and thorough search for the appendix at the time of operation. The danger from infecting the peritoneum, and from too prolonged manipulations increasing shock and prostration, outweighs any benefit which may be expected from a removal of the appendix under the above circumstances.

In searching for this organ, experience proves herself to be a most valuable teacher. The practised finger in most instances is enabled to detect the hard, cord-like body of the appendix, and by careful manipulations to sever its attachments, and bring it up into sight. Its mesentery having been tied off, a ligature is applied as near to the base as possible, and the free portion is cut away.

Some surgeons invert the end of the stump, and bring the serous surfaces together with sutures, a plan that is feasible provided the tissues are not too friable. There are successful operators, however, who do not apply any ligature at all. They imitate Nature in the management of the stump by simply letting it alone, and allowing it to heal by granulation. As patients do well under both methods of treatment, one is not disposed to be too dogmatic in the matter. Personally I use ligatures and sutures in dressing the stump, as I believe in taking every precaution to prevent intestinal leakage, and also to hasten the repair of the parts.

I used to fear that silk placed at the bottom of a suppurating cavity tended to keep open the sinus, and thus to prolong convalescence by acting as a foreign body. I have no doubt that such is the fact in exceptional instances, but I do not think that it occurs often enough to influence our mode of treatment. The objections to catgut are that it is more uncertain in strength and durability, and is less readily sterilized. It is very good for ligation of blood-vessels, but in my opinion it is inferior to silk as a ligature for the appendix.

Fecal fistulæ are not very rare after the removal of the appendix in suppurating cases, but they usually close in one or two weeks of themselves. In rare instances, when complicated with tuberculosis, they do not heal, but serve as a factor in wearing out the patient by malnutrition, and exhaustion. The only permanent fistulæ I have seen in patients, who have in other respects regained fair health, have followed spontaneous rupture of the abscess. I cannot recall one after operation, although it doubtless may occasionally occur. In my own mind I have no doubt that fecal fistulæ and troublesome sinuses depend far more upon the want of vitality in the tissues involved, than upon any particular method of treatment. The key-note of the surgeon's duty is incision and drainage, and so long as that is fairly accomplished, we need not spend overmuch time upon the minor details.

For drainage I prefer the baked gauze, except in deep or large cavities requiring frequent irrigation, when two or more rubber tubes may be used in addition to the packing. In several of my later operations, I have not washed out the suppurating cavity at all, but have contented myself with making a free incision, removing the appendix, when feasible, and establish-

ing good drainage. Thus far the results have been as good as when treated by free irrigation. The latter is especially indicated in cases attended by abundant and fetid suppuration. The peritoneal cavity can neither be drained nor irrigated, when the seat of general adhesive inflammation. However freely the adhesions may be broken up, fresh ones will form within twelve hours, rendering irrigation and all methods of drainage ineffectual and unsatisfactory.

From the fact that many cases seem to be benefited by saline and other cathartics, there will always be a difference of opinion as to their real value in the early stages of appendicitis. The family physician has taught the surgeon some valuable lessons on this point. It is evident that cathartics can do only harm in cases of perforation with no external outlet for the discharges. They not only tend to liquefy the contents of the bowels, but they also increase peristalsis, and thereby may flood the peritoneal cavity with the most deleterious of all substances, liquid feces. Cases of distention from intestinal paresis are made worse by cathartics, as they may cause or aggravate the vomiting, which is a serious symptom in this affection.

After operation and the establishment of drainage, I know of nothing which relieves pain due to distention so surely and so effectually as salines given in small and oft-repeated doses. Few practitioners of experience deny the value of laxatives under these conditions. In the early stages of light or catarrhal cases they very likely are beneficial in establishing intestinal drainage by unloading the vessels of the portal system, as well as by removing irritating substances from the bowels. They are to be used carefully and judiciously, and only in mild cases, and always with the idea in mind that an operation may be necessary at any moment, even after the production of free catharsis. It is the opinion of many practical surgeons, that even the mild cases do as well under the opiate as under the cathartic treatment. While patients often recover under both methods, my own experience leads me to think, that, as a rule, the former is safer than the latter, and that the results are full as favorable.

Opiates are indispensable in the treatment of this affection, and yet the same objection to their use obtains as in strangulated hernia. They may obscure and cover up the patient's real condition. The amount of opiate required is an indication of the severity of the pain, and hence of the character of the attack.

In closing, allow me to say, as I said at the beginning, that this affection is one of the most important that comes to the physician's notice, not only because of its grave character, but because so much depends upon its proper management. Many of the worst cases will die in spite of the most timely and judicious treatment, but more will get well if promptly recognized and carefully managed. One of the most satisfactory reflections which a physician can have is, that he has shown good judgment in the treatment of his patients, and in no class of affections is this fact more evident, than in the prompt recognition and judicious treatment of appendicitis.

[Soon after presenting the above paper the writer was seized with his third severe attack of appendicitis. The first one occurred seventeen years ago; the second two years ago; each lasted about three months. The symptoms of the first two attacks were pain at the epigastrium, marked prostration and emaciation. There were no indications of trouble in the right side of the abdominal cavity. Just a week after the commencement of the last attack, pain, tenderness and muscular rigidity were pronounced in the right iliac region. Three days later laparotomy was performed by Dr. M. H. Richardson. There was an abscess below the brim of the true pelvis and behind the cecum, surrounded by old and fresh adhesions, implicating the sigmoid flexure and the rectum. The appendix was found to be shrivelled up to a small cord, and being firmly incorporated in the dense mass of adhesions was not removed. The principal features of the case were its long duration and unusual location of the symptoms. It was only during convalescence that pain was located outside of the epigastric region. During this time moderate griping at stool was felt behind the pubes, due evidently to the adhesions found at the time of the operation.]

## THE TREATMENT OF UTERINE FIBROIDS, WITH REPORT OF CASES.[1]

BY LEONARD WHEELER, M.D., WORCESTER, MASS.,
*Surgeon to the Memorial Hospital, Obstetrician to the City Hospital.*

In the last four years, 1890 to 1893, I have made notes on 35 cases of uterine fibroids. I have seen, perhaps, 50. Of the 35 cases, I operated on eight — three hysterectomies, four tubo-ovariotomies — and made one exploratory incision. Four were methodically treated by electricity. Two hysterectomies by suprapubic amputation were cured. One complete hysterectomy died of shock. The four tubo-ovariotomies recovered perfectly from the operation — three are now well after nearly or quite two years. The fourth died, perhaps six months after operation, probably from sloughing of a submucous fibroid. Of the four treated by electricity, one remains relieved of dysuria, one flows about as before, one continues to have flowing and dysmenorrhea, and one has died of malignant degeneration.

Case I. Large fibroid. Hysterectomy. Cure.

E. F., thirty-eight years of age, single. Entered Memorial Hospital December 3, 1892. Catamenia at fourteen, and normal up to present illness. Two years ago began to have pain in the right inguinal region, and noticed a hard tumor there. This grew slowly until nine months ago, since which it has rapidly increased. Has had severe hemorrhages, pain, difficulty in micturition, and has grown thin. Now the main tumor extends two inches above the umbilicus. Above this, and reaching to the ribs on the left, is a large, freely movable mass. Further to the right, two other smaller solid masses are felt. By the vagina the uterus is not felt separate from the tumor. Sound enters downward and to the left.

Operation, December 10th. Incision from pubes to a point half-way from umbilicus to xyphoid cartilage. Ascitic fluid four pints; no adhesions. The tumor was lifted out of the abdomen, the upper end of the incision closed with silkworm-gut sutures, and the patient raised to the Trendelenberg position. The right broad ligament extended high upon tumor, its upper edge below the tube being occupied by an elongated, flaccid cyst, the size of small intestine. The ligament was tied off with two silk sutures on outside, clamps on tumor side, and divided. On the left, the broad ligament extended not nearly so high, and was sim-

[1] Read at the meeting of the Worcester District Medical Society, November 14, 1894.

ilarly treated. The wire clamp was applied around the pedicle thus made, pins inserted and tumor removed. The pedicle, something over an inch in diameter, was placed in the lower angle of the abdominal incision, the parietal peritoneum sutured around it and closed above. Skin, fascia and muscle were united with silkworm-gut.

The wound was dressed and the clamps tightened every second day. The sutures were removed on the tenth day. On the eighteenth day the clamp broke, when the top of the stump was trimmed off with scissors, and the wire removed. She was walking about the room in four weeks, and discharged well in seven weeks. At one time there was a sinus through the cervical stump into the vagina, which entirely closed later. Temperature did not go above 101°. Patient has been in good health since.

CASE II. Fibroid, size of fifth month. Hysterectomy. Cure.

L. S., forty-three years of age. Entered Memorial Hospital March 18, 1893. Twice married. One child. Catamenia regular until seven months ago. Two months ago was in the hospital for pain and hemorrhages, and was sent home relieved. Symptoms soon returned, and were now so severe that operation was advised and accepted, the intention being to remove appendages if possible. The tumor extended three inches above the pubes; sound entered behind it. On making the opening into the abdomen, the left appendages were found accessible and removable; on the right side there was a small ovarian cyst with many adhesions. An attempt was made to remove these right appendages, but it was abandoned in favor of hysterectomy. It was difficult, first, to dislodge the tumor from the pelvis; then the pedicle was short, it was hard to get it into the abdominal wound; the bladder was at first caught in the wire loop and had to be peeled down.

The wound was closed and dressed in the usual way. The patient made a good recovery, and was about her room in five weeks. In this case the wire clamp bent, and was cut out of the stump at the end of the second week.

CASE III. Large fibroid. Hysterectomy. Death from shock.

A. J., forty-seven years of age. Entered Memorial Hospital November 18, 1892. Strong family taint of cancer. Catamenia at fourteen, and still regular. Tumor first noticed eight years ago in the left side, and supposed to be ovarian. Has had considerable difficulty in micturition, but the main symptom is a distinct failure in general health for the last four months. The abdomen is filled, from the pubes to the ribs and from ileum to ileum, with a hard, somewhat nodular mass; girth 32 inches. By vagina the tumor bulged the posterior wall far down. The sound passed backwards and to the right three inches.

Operation at 11 A. M., December 29th. The first incision failed to reach any peritoneal cavity. It was extended nearly to the level of the ribs, and the cavity entered above the tumor. The solid tumor was found to occupy the left broad ligament, splitting its folds and lifting the anterior layer from pelvic floor and anterior abdominal wall, carrying along with it the bladder, which was thus intimately attached to the tumor three or four inches above the pubes. This mass was attached to the uterus through its whole length, and crowded it far over to the right. The right broad ligament was occupied by an elongated cyst of the ovary lying behind the uterus and fibroid, and serving as a fulcrum to tip the cervix above the symphysis. The diameter was, perhaps, three inches, length six or eight inches. This cyst separated the folds of the ligament, and was close against the uterus. The fibroid was lifted from the abdomen, the upper part of the incision closed to retain the intestines, and the patient put in the Trendelenberg position. The sigmoid flexure was found firmly adherent on the *right* side of the tumor posteriorly. It was necessary to leave a piece of the tumor on the intestine. In attempting to separate it, a little opening was made through the intestine. It was closed with four Lembert sutures. The peritoneum was separated from the tumor as far as possible, and with it the bladder in front. A small tear was made in the wall of the bladder, but it was immediately sutured. This separation could be very well done on the left, but on the right a massive, fleshy, broad ligament had to be tied off in its whole length. The uterine arteries were secured on both sides by these ligatures, and the whole uterus removed with the tumor. The wound now left from the extensive enucleation on the left side and the long, thick, broad ligament on the right was of wide extent. The peritoneal flaps, however, covered it well. An iodoform gauze drain was drawn through the vagina, and the abdominal wound closed without further drainage. After being put to bed a quart of salt solution was passed into the median basilic vein, in addition to the usual measures for the treatment of shock; but the patient did not recover, and died at 8. P. M.

CASE IV. Fibroid, size of fifth month. Tubo-ovariotomy. Symptoms relieved.

A. B., thirty-six years of age, married. Entered Memorial Hospital, December 20, 1890. Four children. Miscarriage five years ago, not well since. Menses irregular and profuse during this time. Patient has a hard, symmetrical fibroid, extending half way to the umbilicus. It was impossible to introduce a sound.

January 16th, the ovaries were removed. They were easily accessible, and there were no adhesions. She had considerable hemorrhage on the third and fourth day per vaginam. Patient was discharged well in three weeks. I have heard from her from time to time since; she has had no recurrence of symptoms.

CASE V. Large multilocular fibroid. Tubo-ovariotomy. No permanent relief.

M. M., colored, thirty-five years of age, married. First entered Memorial Hospital, December 30, 1890, when a fibroid double the size of a hen's egg was removed from vagina. It was attached to the lower part of the uterus by a pedicle one inch in diameter.

In May, 1892, she passed naturally, by the vagina, a fibroid as large, according to her own statement, as a man's fist.

August 28th of the same year, having just been admitted to the hospital, she was delivered in the same way of another fibroid as large as two fists. After this she was discharged, and readmitted September 24th. The record of physical signs October 12th, is as follows: Tumor reaches nearly to umbilicus, is in two large lobes — one anterior and nearly median, the other posterior and to the right.

October 22d, tubo-ovariotomy was done. The tumor, reaching nearly to the umbilicus, so occupied

the broad ligaments as to leave the pedicles very short, and in removing the ovary bits of ovarian tissue were left on the stump on each side; these were thoroughly cauterized. The patient made a normal recovery, and was discharged well in three weeks.

Four months later she had a considerable hemorrhage of three weeks' duration. Now, two years after the operation, the tumor has very much increased in size, and she is having a good deal of hemorrhage. A hysterectomy would have been the proper operation.

Case VI. Fibroid filling the true pelvis, causing pressure symptoms. Tubo-ovariotomy. Woman two months pregnant. Goes to term. Symptoms relieved.

K. G., thirty-eight years of age. Entered Memorial Hospital, March 18, 1891. Married two years. Catamenia regular until nine weeks ago; none since. No symptoms until four days ago, when she became unable to pass water. She has required the catheter since. The pelvis was found to be quite fully occupied by a fibroid which crowded the uterus tightly forward against the pubes. Laparotomy was done March 24, 1891. The tumor filled the pelvis very closely, the ovaries lay so far behind it as to be difficult of access; still by twisting the tumor from one side to the other they were reached and tied off. The ligature on the left side slipped off, leaving a long wound along the upper edge of the broad ligament. Considerable time was spent in securing the bleeding points. A rubber drainage-tube was left in for two days. She was discharged well at the end of three weeks.

This patient was confined at term of a living child on November 8th following, and must have been about two months pregnant at the time of operation.

Case VII. Fibroid, size of seven months. Tubo-ovariotomy. Temporary relief. Death, six months later, from sloughing fibroid.

H. K., thirty-five years of age. Entered Memorial Hospital, April 16, 1891. Married nine years. Catamenia at twelve, and regular till one year ago. Since that, increasing hemorrhages; pain, too, has been severe, requiring opiates. She is becoming exhausted by pain and loss of blood. The tumor was first noticed one and a half years ago; it now fills the pelvis, crowding the uterus forward, and extends above the umbilicus.

Operation, April 22d. The appendages were removed with considerable difficulty, there being a hemato-salpinx the size of a goose's egg on the left side, the right appendages being concealed far down behind the tumor, and both having adhesions.

The patient made a good recovery, and was discharged May 8th. She died six months later, probably from septicemia caused by a sloughing, submucous fibroid.

Case VIII. M. W., forty-nine years of age. Entered Memorial Hospital, January 30, 1890. Twice married, the last time six years ago. One child thirty years old. Not so well since her last marriage. Fell one year ago, and since that has had pain in her side and back. Per vaginam, uterus deflected to the right. On the right of the uterus, and connected with it, is a rounded hard tumor the size of a goose's egg.

Laparotomy was done, and a small fibroid was found in the right broad ligament, attached along two-thirds the length of the uterus. The woman being past the menopause, nothing was done, the symptoms not being sufficiently severe to justify a complete hysterectomy, which was the only way of removing the growth. The patient made a smooth recovery, and was temporarily greatly relieved by the operation.

I have used electricity, Apostoli's method, in cases of various kinds, but have records of only four cases of uterine fibroid, systematically so treated.

In one case, a woman of fifty-four, with a tumor the size of a child's head, where hemorrhage was the important symptom, sixteen applications relieved the flowing and greatly improved the condition of the patient. Three years later she died of malignant disease of the uterus and pancreas.

The second patient, forty years old, with a tumor of the same size, also with severe metrorrhagia, received no benefit.

The third case got temporary relief for very severe hemorrhage and pain.

The fourth case was quite relieved of dysuria.

The history of the surgical treatment of uterine fibroids begins with the publication of Kimball's (of Lowell) case in the *Boston Medical and Surgical Journal* in 1855. The first case was successful, and was followed by two unsuccessful cases operated on in the same way. The pedicle was tied with silk, dropped into the abdomen, and the ligature brought out at the lower angle of the wound. No further step was made for nearly twenty years.

In the early seventies Koeberle and Péan improved the operation, and established it on a scientific basis. The silk ligature was replaced by a wire clamp, and instead of being dropped back into the abdomen, the pedicle was fixed in the wound by long pins, and the peritoneum nicely sutured around it.

Then came the period of aseptic surgery, and renewed attempts at the intra-peritoneal treatment of the pedicle. These attempts resulted in what has been called Schroeder's method, where a wedge-shaped piece is removed, and the flaps of the pedicle thus left are united by tier sutures, the peritoneum being closed over all. Péan had obtained a mortality of 34 per cent. Schroeder reduced it a little, to 30 per cent. Martin, of Berlin, by the use of Schroeder's method with the addition of drainage through Douglas's pouch, got 22 per cent. Zweifel (Leipsic) in 1889 using a continuous chain suture of silk running across the pelvis from side to side, including both broad ligaments and the uterine stump, had a series of 22 successful cases.

At present the operation of abdominal hysterectomy is done in four different ways. The method by fixation of the stump in the abdominal wound still has followers, pre-eminently Bantock in England and Price in America. By several operators the pedicle is left in the peritoneal cavity. Others treat the pedicle extra-peritoneally on the floor of the pelvis, that is, after amputating the uterus the pelvic peritoneum is united over it, or finally a complete hysterectomy is done.

The results obtained by these different methods by large operators are all excellent, and vary astonishingly little. For instance, as reported at the International Medical Congress held this year in Rome, Martin reported a series of 26 cases, with one death, a mortality of 3.8 per cent.; de Ott, 24 cases, with one death; Bantock, 23 cases, with one death; Carle, 20 cases, with no death; Zweifel, 93 cases, with three deaths. Leopold [1] reports 20 cases, with no death, and mentions Brennecke's report of 19 cases with no

[1] Centralbl. f. Gyn., No. 26, 1894

death, making in all 225 cases with six deaths, a mortality of 2.6 per cent. These are selected statistics, and by no means represent the present average rate of mortality for the operation of hystero-myomectomy. Still it is a fact that five years ago the general mortality of the most frequent operators was 25 per cent., while now the same class of men have a mortality less than one-third as large.

In this country also the tendency is towards the operations of complete hysterectomy and supra-vaginal hysterectomy. At the meeting of the American Gynecological Society May, 1893, there were reported [3] from Polk 30 cases, with two deaths; Mann, 13 cases, with one death; Krug, 25 cases, with two deaths. Baer, in September, 1893, reported 37 cases, with two deaths.[4] Eastman,[5] 79 cases with eight deaths; Kelly [6] 50 cases, with three deaths; Baldy,[7] 41 cases, with four deaths; Edebohls [8] six cases, with no death. In all, 281 cases, with 22 deaths, a mortality of 7.8 per cent. If I were able to bring the American reports to as late a date as the foreign ones, the showing would undoubtedly be somewhat better still. This operation has been especially promoted by Polk of New York. He first described it in a paper read at the annual meeting of the American Gynecological Society in 1892. It consists in tying off the broad ligaments, making anterior and posterior peritoneal flaps, by peeling the membrane from the uterus, tying the uterine arteries, cutting through the vaginal junction, uniting peritoneum with vaginal wall anteriorly, posteriorly and laterally, with long catgut sutures, drawing these ligatures into the vagina and filling the vagina with iodoform gauze. Polk's record in May, 1893, was 30 cases, with two deaths, as stated above.

On equal footing with this plan stands the method of amputation of the uterus just above the vaginal junction, thus leaving a small uterine stump. Some operators constrict this stump in one mass; others in two or three portions; while others still, tie the uterine artery just as in Polk's operation, putting no ligatures on the stump. The best results in this kind of operation have been published by Baer of Philadelphia, and Zweifel of Leipsic. Baer ties the arteries, leaves only the vaginal portion, and this unligated, does not touch the cervical canal, and uuites the peritoneal flaps over the stump. Baer's latest statistics were 37 cases and two deaths. Kelly, after tying the uterine arteries, dissects the vesical peritoneum, amputates the tumor, cups the pedicle, brings the flaps together with silk sutures, and unites the peritoneal flaps over all with a continuous suture. He reports 50 cases, with three deaths. Zweifel, ties the broad ligaments with two interlocking silk ligatures, puts on an elastic ligature, removes the tumor by a wedge-shaped incision into the pedicle, then continues the interlocked suture, using catgut for uniting the stump flaps. He has published a series of 93 cases, with three deaths.

A few operators still adhere to the wire clamp and pedicle pins, but the results by total hysterectomy and supra-vaginal hysterectomy, with closure of the peritoneum over the stumps, have reached such a degree of excellence that the near future will probably see the abandonment of the old extra-peritoneal method.

The figures which I have quoted bring the operation of hysterectomy up to a level in point of success with ovariotomy. This accomplished, the question of indications for the operation has to be reviewed. The surgeon who counts upon 90 per cent. of cures, looks at the question quite differently from one who expects only 75.

The rule used to be to operate only on those cases which threatened the life of the woman or made it unendurable, now the surgeon finds no little favor who advocates hysterectomy for a very moderate amount of discomfort caused by the presence of a uterine fibroid. As always happens in such cases the ardor of success carries men too far; and not only is operation advised where it seems unnecessary, but, on the other hand, the dangers of uterine fibroid are unduly exaggerated, and a bold attempt is made to shake our faith in the old established belief that the menopause has an inhibiting influence on its growth, and that spaying for a fibroid is a reasonable procedure. And this attempt is indeed, in a degree, successful, for we no longer believe a fibroid of the uterus to be quite the innocuous thing we have been taught. Matthews Duncan exclaimed, "Who ever knew a woman to die of fibroid tumor?" I can recall four in my own experience. Many of you will be able to remember such cases; and we all know how unreliable a mere effort of memory is in these matters. I have heard an old practitioner deny that he ever had a case of ruptured perineum in his practice. The indication for surgical interference, however, is not so often impending death as the incapacity for enjoyment or utilization of life, brought about by pain, hemorrhage or pressure sequelæ.

At present it is useless to lay down exact indications for the operation; they vary according to the skill of the operator and the circumstances of the patient. The tumor which incapacitates a poor woman for work or the care of a family must be operated on, while the same tumor in a woman not obliged to work could be taken care of symtomatically without trouble.

As to tubo-ovariotomy, it has a mortality among the best operators of five per cent.; its field of operation is necessarily limited, and its results more or less uncertain. Under these conditions its range of application must, I think, grow less and less as the success of hysterectomy increases, although Pozzi, writing in 1890, says, "The number of surgeons who still prefer the operation of hysterectomy in all cases is becoming continually smaller." So rapidly are changes taking place nowadays in the field of abdominal surgery.

The question of electrolytic treatment of fibroid has been the cause of vigorous argument, and is not yet settled. To me it seems as though much good can be accomplished by it in relieving symptoms and restoring general health, though there is no doubt that the relief will oftentimes be temporary. The hope that it can cause any important diminution in the size of the tumor must be given up. It is certainly the best treatment in cases where for any reason an operation is not admissible.

LONDON has sixty ambulance stations for the six thousand accidents that occur on her streets each year.

# Clinical Department.

## A CASE OF CONGENITAL DIAPHRAGMATIC HERNIA.

BY GEORGE G. SEARS, M.D.

The subject of these notes was born in the Boston Lying-in Hospital during my term of service as resident physician, and for the privilege of reporting them, I am indebted to Dr. W. L. Richardson.

The child, an apparently perfectly formed, seven-pound boy, was born in December, 1885, after an easy labor, the second stage lasting but an hour. Immediately after birth it gave two or three short, sharp cries, and then, though it seemed to make every effort, it was unable to produce a sound. Respirations became gradually shorter and quicker, cyanosis deepened, and death resulted an hour later. The only abnormality found was the position of the apex-beat in the right axillary line. Only a most superficial physical examination, however, was made, as all our efforts were concentrated in encouraging his attempts to breathe. The autopsy was made by Dr. W. F. Whitney, who found the following condition:

"The greater part of the small intestine, with the stomach and spleen, were found in the thoracic cavity, into which they had passed through a hole occupying the greater part of the left side of the diaphragm. The left lung was reduced to a single lobe (the upper), and pressed upwards and forwards. The right lung was normal, but pressed upward by the heart which was in its pericardium in the lower part of the right pleural cavity. The lungs were compressed, but could be distended. Nothing else abnormal noticed."

Although similar conditions are comparatively rare anomalies, they are yet sufficiently common for Lacher,[1] in 1880, to have collected 276 cases, including both the congenital and acquired forms, while Thoma[2] two years later collected 291, and since then a number of others have been reported. They have been found in patients of all ages, and have frequently remained latent for years and even till death, neither preventing men from leading active lives nor women from passing successfully through a number of pregnancies. Others, however, have caused more or less distressing symptoms, which are referable to a disturbance of the functions of the thoracic or digestive organs. They have not always proved incompatible with long life, even when the defect in the diaphragm was apparently as great as in this case, for Thoma gives the history of a man, fifty years old, in whom its left half was almost entirely wanting and the thorax contained the fundus of the stomach, at least half of the small intestine, a considerable portion of the transverse colon, the spleen and a greater part of the omentum. The direct cause of death was a right pleuro-pneumonia. From the limited respiratory area acute pulmonary affections not infrequently terminate these cases, when death does not result, for mechanical reasons, immediately or a very short time after birth.

Much less frequently strangulation has proved the cause of death, since diaphragmatic hernia are subject to the same accidents as those in other situations, and its possibility should therefore always be considered in obscure cases of intestinal obstruction. One such case, reported by Abel, is especially interesting because the correct diagnosis was made and surgical relief attempted, but the patient unfortunately died three hours and a half after the operation.

The size and contents of these herniæ have varied from a small bit of omentum to half the contents of the abdomen. According to Lacher the only organs, which have never been present, are the urinary bladder, the rectum and the genitals, but diagnosis is not possible clinically, unless the stomach or bowels have invaded the thoracic cavity. Typical cases — where the abdomen is retracted; the affected side of the chest expanded, tympanitic, and with little or no respiratory movement; the intercostal spaces bulging; the apex-beat and area of cardiac dulness absent or displaced; and on auscultation the possible presence of metallic tinkling or other musical sounds — would seem easy of diagnosis, confusion with a pyo-pneumothorax being the most likely source of error; but practically only about half-a-dozen cases have been correctly made out, and in most of these the diagnosis was considered only probable. The most reliable and constant sign is cardiac displacement, especially in left-sided herniæ, which are six times more frequent than right, since the usual causes can always be readily eliminated. Congenital transposition of the heart might lead to mistake, but the more frequent error seems to have been made in taking the displacement due to herniæ for a simple dextro-cardia. The amount of dislocation may vary at different examinations, according to the amount of distention of the thoracic portion of the stomach or bowels; and in doubtful cases Abel suggests the careful introduction of water into the stomach by means of a tube, and noting the position of the heart as water is added or withdrawn. Failure to arrive at a diagnosis has not always resulted so much from a lack of distinctive signs and symptoms as from oversight on the part of the physician; yet when over 300 reported instances can be collected, it is not so rare that the possibility of its occurrence should be forgotten in making a differential diagnosis between conditions which it may simulate.

## A FATAL CASE OF POISONING BY MAYO'S VEGETABLE VAPOR.

BY F. E. SWEETSIR, M.D., MERRIMAC, MASS.

John S., the patient, was a boy nineteen years of age, strong, well developed and muscular, never having been ill before. He was given Mayo's vegetable vapor December 20th, at 9.30 A. M., for the purpose of having two teeth extracted. The amount given was rather less than the average dose, about eight gallons, which he seemed to take easily. The teeth were extracted without pain and he apparently came out of the anesthetic normally.

After talking with the dentist about having some teeth filled, he left the office, apparently a well boy, and walked to his home a quarter of a mile distant. When he arrived there, however, he complained of feeling ill, and his condition was such that his mother became alarmed and sent for me.

I saw him at ten o'clock, about half an hour after he had inhaled the vapor. He at that time was apparently in a dying condition. His face and extremities were deeply cyanosed, and covered with cold

perspiration; pulse 170; respiration 34. He was conscious, and answered questions intelligently; but he was stupid, and was raising much frothy mucus and saliva. I immediately gave him hypodermically one-thirtieth of a grain of sulphate of strychnine, one-fiftieth of a grain of digitalin and half an ounce of brandy. Hot-water bottles were placed around him; and with plenty of coverings his couch was moved near an open window, although it was a very cold day. The dentist who gave him the anesthetic worked with me over the patient about four hours giving him in the meantime all the heart stimulants at hand, including nitroglycerine, aromatic spirits of ammonia and digitalis. The circulation improved; and at noon the pulse was 130, cyanosis less marked, and he said he felt better.

At 2 P. M. the heart-beat was 120 to 130, and the cyanosis had largely disappeared. At this time (2 P. M.) I left him, with instructions to the dentist to see him in an hour, and if he did not seem as well to call in a fellow practitioner, as I should not be able to come again until six o'clock.

His attendants said that he seemed improving until four o'clock P. M., when he slipped from the couch on which he was lying to the floor. They told him to let them aid him; but he insisted he was all right, sprung to his feet, and died in a very few moments of paralysis of the heart.

Personally, I have always denounced Mayo's vapor, it being prepared by a secret process; and as such I think it should not be used. In this section of the country dentists tell me it has been advertised to such an extent that a dentist has to have it in order to do business. Patients call for it, and will have nothing else.

This same dentist took from the same cylinder, the Sunday before, two gallons more of the vapor than this unfortunate boy inhaled, with no ill effect, while I lanced an ulcerated tooth for him.

The autopsy upon the patient showed great venous congestion of the lungs, the heart a third larger than normal; and the mitral valve consisted of practically only one large flap, which condition seemed to be congenital. This flap closed the orifice very well, so that there could have been but little leakage during life; and the closest questioning of the mother could bring forth no evidence pointing to any heart trouble. Other organs were normal.

I have never read or heard of an accident of this kind. All the fatalities from this anesthetic that have occurred have been in the chair and while under the anesthetic, not six hours afterward and after a walk of a quarter of a mile apparently in a normal condition.

## Medical Progress.

### RECENT PROGRESS IN DISEASES OF THE NERVOUS SYSTEM.

BY PHILIP COOMBS KNAPP, A.M., M.D.

(Concluded from No. 4, p. 83.)

#### SYPHILIS OF THE SPINAL CORD.

THREE years ago Erb[7] described a form of spinal paralysis of syphilitic origin characterized by spastic paralysis of the lower extremities, marked increase of the tendon reflexes, slight muscular spasticity, disturbances of micturition, and comparatively slight disturbances of sensation. Sachs[8] emphasizes the fact that there may be other forms of syphilitic spinal paralysis. In one case there was a flaccid atrophic paralysis with rapid recovery, and three cases were of a spastic type, with marked contracture, pronounced atrophy and sensory disturbances, and varying vesical symptoms. Sachs considers that the characteristic features of spinal syphilis are the distribution of the morbid process over the entire cord, with simultaneous involvement of all three portions; the slight intensity of the morbid process compared to its extent, some functions of the cord being retained while others are lost; a rapid change in some symptoms with obstinate persistence of others; and the frequency of earlier symptoms in the cord or in other parts of the nervous system. These conditions may permit the diagnosis of syphilis.

Gerhardt[9] thinks that most cases of spinal syphilis are due to disease of the vessels and membranes, which later involves the cord. Important symptoms for diagnosis are rigidity of the spine, shooting pains, girdle pains, paraplegia, and Brown-Séquard's paralysis. The cause of Erb's type of syphilitic paralysis is thought to be due to multiple lesions of the roots. Only rarely does syphilis give rise to symptoms of muscular atrophy, poliomyelitis anterior, or Landry's paralysis.

Lamy,[10] after a study of several cases of spinal syphilis, concludes that the commonest affection is a diffuse meningo-myelitis, accompanied by disease of the blood-vessels. The changes in the meninges and vessels are primary. There may be a syphilitic lepto-meningitis and pachymeningitis; the latter is most commonly situated in the cervical region. Spinal meningitis is often accompanied by cerebral meningitis, which is usually situated at the base of the inter-peduncular region and about the chiasma. The changes in the blood-vessels are first noted in the adventitia of the veins. The symptoms of meningeal disease are to be distinguished from those of disease of the cord. The prodromal period is characterized by meningitic pains in the back or head, ocular paralysis, and more or less severe cerebral symptoms. The second stage is characterized by spinal paralysis, usually presenting the type of a moderate transverse myelitis, spastic paresis of the legs with slight impairment of sensation and slight involvement of the sphincters. In the minority of cases the paralysis is acute and severe, and, if not treated, leads rapidly to death.

Kuh[11] has collected 62 cases of Erb's type of syphilitic spinal paralysis and allied forms with six autopsies, and he considers that syphilis is not infrequently a cause of myelitis. The disease began in 36 out of 52 cases within six years after the infection. In some cases cerebral symptoms are first noticed, but usually the trouble begins with increasing weakness and stiffness of the legs, often accompanied with paresthesia, or a girdle sensation. Pain is seldom severe. Anesthesia is less common. With the weakness of the legs there is very apt to be some disturbance of micturition, and loss of sexual power. The weakness is very apt to be greater in one leg, and seldom increases to complete paralysis. Contractures

[7] Neurolog. Centralblatt, March 15, 1892.

[8] Brain, Part lxiii, 1893.

[10] Nour. Iconographie de la Salpêtrière, No. 4, 1893.

[11] Deutsche Zeitsch. f. Nervenheilk., iii, 359, 1893.

are rare, but the reflexes are always increased. The course of the disease is very chronic and progressive. The prognosis, under proper treatment, is much more favorable than that of ordinary myelitis; 11 per cent. recovered, 70 per cent. were improved, and 7 per cent. died. Relapses, however, may occur. The lesions are chiefly in the dorsal cord, and in the posterior part of the lateral columns; later the posterior cornua and posterior columns may become involved. As a rule, the meninges are little affected, the trouble being due to syphilitic changes in the smaller vessels of the cord — the marginal vessels of Adamkiewicz.

### LIGATURE OF THE CAROTID.

In an appendix to a study of tumors of the parotid Kopfstein [13] has studied the cerebral symptoms which may follow ligature of the carotid, which is of much interest on account of the occasional necessity of tying the carotid as a preliminary to certain operations on the brain.

Pilz observed cerebral symptoms after ligature of the carotid in 165 out of 520 cases; Ehrmann in 22 per cent., Lefort in 30 per cent. Among the symptoms are headache, paresis, paralysis, coma, etc. One of the rarest symptoms is aphasia, which occurred only twice in Pilz's cases; once there was no paresis, and once there was hemiplegia on the opposite side. In general the cerebral symptoms after trauma are more common than those after ligature rendered necessary by any other special cause. In most cases the trouble is due to a simple ischemia of the hemisphere. The symptoms cease when a collateral circulation is established. Paresis or paralysis does not come on at once, because the brain is still saturated by the nutritive liquid. If the basal arteries are not sufficiently developed, or if they are atheromatous or occluded, the insufficient nutrition may lead to changes of structure. In such cases the autopsy shows cerebral softening. In other cases the cerebral symptoms may be due to purulent processes or to embolism. Maydl gives the following data for prognosis: When hemiplegia comes on at once or within twenty-four hours, the prognosis is bad, especially in alcoholism, syphilis, and subjects with spontaneous aneurism; hemiplegia coming on long after ligature suggests suppuration on the surface or within the brain. Death may occur suddenly or after some weeks of apparent health, as in all cases of cerebral abscess. Hemiplegia after thrombosis of the carotid extending to the basal arteries usually comes on in from three to eleven days after the ligature, and it may disappear slowly or lead to death in a few hours or eighteen days.

### EYE-STRAIN AND EPILEPSY.

Dodd [14] has studied the relation between errors of refraction and epilepsy in 100 epileptic patients. He found much less hypermetropia than in normal individuals, and much more astigmatism. In 100 epileptics there was 42 per cent. of simple hypermetropia, and 42 per cent. of astigmatism; in 50 normal persons there was 70 per cent. of simple hypermetropia and 16 per cent. of astigmatism. Twenty-five patients did not need glasses; 75 were ordered to wear glasses, and of these 52 reported. Thirteen had no fits while wearing glasses, during a period of from four months to a year; three remained *in statu quo;* and 36 improved while wearing glasses. Dodd claims that errors of refraction may excite epilepsy, and that in many cases the correction of such errors, combined with other treatment, will cure or relieve the epileptic condition. In some cases, where the error of refraction has been corrected the epilepsy will continue, generally in a modified form, in consequence of other irritation, even though the error of refraction may have been the exciting cause of the fits in the first instance.

Hern [15] in five cases of epilepsy, by partial correction of the error of refraction succeeded in diminishing the number of attacks in two cases, and in checking them entirely in one, the attacks returning when the patient no longer wore glasses. Stephenson, in the discussion that followed, urged the necessity of distinguishing between epileptic and hysterical attacks. In the latter any new form of treatment will often act favorably for a time.

Martin,[16] as the result of a series of observations, thinks that neither astigmatism nor hypermetropia can often be regarded as a cause of epilepsy, and that the correction of these conditions by proper glasses have no influence on the disease. Nevertheless he thinks that Stevens's observations indicate that epilepsy can in many cases be benefited by optical means, and that we should therefore in every case of epilepsy investigate the refraction.

[Dodd's statistics are apparently very encouraging, but we must remember that none of his cases were under observation for more than a year, and few of them more than a few months, and that most of them were given bromides; and also that many cases of epilepsy do very well for a short time under any change of treatment. Martin's conclusions from his own work seem far more in accordance with the best views upon epilepsy, than do the later conclusions which he is led to draw from Stevens's statistics. The influence of eye-strain in producing epilepsy seems to us extremely problematical.— REP.]

### ANGIONEUROTIC AND HYSTERICAL EDEMA.

Higier [17] discusses the acute circumscribed edema of the skin, first described by Quincke, which may accompany various neuroses, but which is more commonly an independent and obstinate affection. It may affect both the skin and the mucous membranes. Among the etiological factors are heredity, the neuropathic predisposition, local chilling of the skin, alcoholic excess, and physical and mental emotions. Vomiting, colic, hemorrhages from the mucosa, hemoglobinuria, and effusions into the joints are observed in the recurring forms. Rarely it has the character of an infectious disease. It lasts from a few hours to several days. It is probably of nervous origin, as is shown by the following facts: its preference for neuropathic individuals, the occasional direct inheritance, its onset after physical exhaustion or psychical trauma, the nervous symptoms which accompany it (paresthesia, neuralgia, colic), its occasional unilateral localization, and its improvement with the improvement in the nervous condition. Four cases were reported, three men and one woman. In one the edema was localized on the glabella and often came on after emotional disturbance; in another it affected the mucosa

[13] Casopis ceskych lékarn., Nos. 4 to 6, 1894. Ref. in Revue Neurologique, No. 14, 1894.
[14] Brain, Part lxiv, 1893.
[15] British Medical Journal, Sept. 30, 1893.
[16] Journal de médecine de Bordeaux, No. 13, 1893.
[17] 66 Versammlung deutscher Naturforscher und Aerzte in Wien. Neurolog. Centralblatt, Oct. 15, 1894.

of the mouth and pharynx, and came on after taking even a very small dose of antipyrine. In three cases there was a neuropathic condition, but no heredity. In the fourth case the patient was perfectly sound, but he had obstinate constipation with increased intestinal putrefaction. In only one case was there no recurrence. One case had slight albuminuria during the attack, and the edematous spot was warmer and white or reddish. Fever was never observed. Unless there is a removable cause the prognosis is bad, one case having seventy attacks in a year. Treatment is often futile.

The chronic form of angioneurotic edema is seen almost without exception in hysteria, but it is quite rare. The four cases reported occurred in young women, and in two cases it was diagnosticated as phlegmon, and once as osteomyelitis. No cause could be determined. It began with pain and paresis, and once with redness and local heat. The localization is unilateral, or in the region of the ankle, the forearm, or the hand and wrist. Its characteristic features are a hard swelling, elasticity, a pale color, and an increase of the edema in the morning, but these symptoms are not constant; in one case the edema at first was soft. Pallor is much less important. Sydenham speaks of a white hysterical edema, but in Higier's cases it would be proper to speak of it as red or variegated. The swelling is not always cold; the one case where the edema was reddish the temperature was increased. In only one case did the edema vary in intensity. When the cardinal symptoms are absent the diagnosis is difficult. One case seemed like an arthritis, and the diagnosis was established only by hypnosis and the occurrence of an hysterical attack. The swelling is often accompanied by local arthralgia, myalgia, paresis, cutaneous hyperesthesia or anesthesia, or vaso-motor and trophic disturbances. In two cases there was recurrence. The shortest duration was three months, the longest a year. In one case the edema recurred three times by auto-suggestion.

## Reports of Societies.

### MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

TWENTIETH ANNUAL MEETING, AT HOT SPRINGS, ARK., NOVEMBER 20-23, 1894.

(Concluded from No. 4, p. 89.)

THIRD DAY.— MORNING SESSION.

DR. FRANK P. NORBURY, Jacksonville, Ill., read a paper entitled

THE MENTAL SYMPTOMS OF CEREBRAL SYPHILIS: A CLINICAL STUDY.

He drew the following conclusions:

(1) Somnambulism and allied states; lapses of intelligent conceptions, with associated loss of memory, are mental symptoms of cerebral syphilis.

(2) Sudden somnolence, with ocular spasm or paralysis, points to syphilis; when preceded by headache and monoplegia, it is almost pathognomic. Headache, quasi-periodical, as defined by Gray, with marked insomnia, suddenly ceasing and followed by psychical disturbance, is due to syphilis.

(3) Melancholia or mania, when following periodical headaches, insomnia, or somnolence, is to be classified thus:

(*a*) With ocular spasm or other form of monoplegia or heterogeneous paralysis, it is due to syphilis. (*b*) Pseudo-paranoia. By this he means that cases presenting all the symptoms of paranoia, systematized delusions depending on hallucinations of sight, hearing, taste or smell, with slight impairment of general mental functions, are due to syphilis; as we know that syphilis causes isolated local losses of power, and it is noteworthy when the special senses are involved that mental derangement usually results. (*c*) Pseudo-paresis, characterized by fibrillary tremor of tongue, indistinct speech (partial or complete aphasia), uncertain and trembling gait, with delusions of grandeur, and occasional outbursts of maniacal excitement, pupillary involvement, all characteristic symptoms of paresis, but which yield readily to antisyphilitic treatment, may be said to be due to syphilis.

(4) Class four have had epileptiform and apoplectiform attacks. We find cases in which treatment was undertaken too late. The symptoms are those of terminal dementia, only occurring in patients of previously sound mental condition and with no special hereditary history.

DR. CHAS. B. PARKER, of Cleveland, O., contributed a paper on

THE SURGICAL TREATMENT OF INJURIES OF THE HEAD,

in which he presented the following conclusions:

(1) In any case of doubt as to the character of a head injury, explore by incision, if necessary.

(2) In the case of wounds, especially the smaller and punctured, enlarge them for exploration and cleansing.

(3) In all cases of fracture, depressed or fissured, operate, elevating the depression and exploring the fissure for a depression of the inner table, which so often occurs.

(4) Leave the principal fragments of bone after elevation, if surgically clean, even if entirely detached from the dura mater and pericranium, thus averting cerebral hernia, vertigo and other cerebral disturbances.

(5) All these operative measures should be conducted under the most rigid aseptic and antiseptic measures.

DR. B. MERRILL RICKETTS, of Cincinnati, read a paper on

(A) CASTRATION FOR HYPERTROPHIED PROSTATE; (B) REMOVAL OF HEAD OF FEMUR FOR DISLOCATION INTO LESSER SCIATIC NOTCH; (C) TREPHINING FOR PRESSURE AS A RESULT OF FLUID IN ACUTE CEREBRAL MENINGITIS.

In a case of castration for hypertrophied prostate, the author said he was inclined at first to make a suprapubic operation, possibly combining the suprapubic and perineal. After thoroughly considering the matter and explaining to the patient the probable results of the various operations, he decided to remove the testicles. After having the patient under observation for ten days, he proceeded to operate, removing the testicles. The arteries were twisted, the wound closed, and integument coapted with a continuous silkworm-gut suture. The patient rallied well from the chloroform, and suffered no inconvenience or pain

thereafter. The wound was examined on the fourth day, and primary union was found to have taken place. The patient left Dr. Ricketts's private hospital at the end of the sixth day. On the second day after the operation the patient told him that he could urinate with greater ease, and that the pain was slight; that he could sleep four hours at a time during the night, whereas formerly he had been getting up once every hour. This condition continued to improve during the patient's stay in the doctor's hospital.

TUMOR ALBUS OF THE KNEE-JOINT.

This paper was read by DR. WILLIAM E. WIRT, of Cleveland, O. The object of the paper was to present a summary of the points to be observed in the treatment of tumor albus of the knee-joint, and to call attention to the fact that most excellent results are obtained by the use of conservative measures. The author classified the treatment under the two headings of constitutional and local measures, and the local under the subdivisions of conservative and operative treatment.

DR. A. H. MEISENBACH, of St. Louis, read a paper on

RESECTION OF THE KNEE FOR SEPARATION OF THE LOWER EPIPHYSIS OF THE FEMUR.

The case was of two years' standing in a patient thirteen years of age. The author said separation of the epiphysis is a condition that may occur either on account of trauma or disease. There seems to be a difference of opinion among writers as to the frequency of its occurrence, especially as the result of trauma. As the result of disease of the bones (osteomyelitis), it is considered a not infrequent accident. Traumatic separation of the lower end of the femur occurs in about from one-fifth to one-third of all the reported cases, and in the majority of instances previous to the sixteenth year, seldom later. The forces that are necessary to produce this separation are various. Thus, during childbirth traction may produce it. Volkmann states that he has produced it when the hip is diseased, when making rotation in seeking for crepitation, or extension in the application of plaster-of-Paris dressings. Other forces are indirect external violence, usually of a twisting character, or lateral or at right angles to the axis of the limb. The readiness with which the dislocation of the separated diaphysis into the popliteal space occurs can be explained (1) on account of the anatomical structure of the surrounding parts; (2) the force and position of the patient, the popliteal space being in the direction of least resistance, while on the anterior aspect we have the quadriceps tendon, the patella, and the ligamentum patellæ. The occurrence of pathological separation of the epiphyses is regarded by the latest writers on surgical pathology and diseases of the bones as a not infrequent accident in diseases of the bones and joints. It is noted in osteomyelitis of the long bones.

THIRD DAY.— AFTERNOON SESSION.

TREATMENT OF TRAUMATIC CATARACT, ATTENDED WITH RAPID SWELLING OF THE LENS,

by JAMES M. BALL, of St. Louis, Mo.

For years the subject of traumatic cataract has been a *bête noir*. Cases of lenticular opacity caused by a foreign body which remains within the eye, are always extremely dangerous, owing to the introduction of pathogenic germs on the one hand, and the danger to the sympathetic ganglia on the other. Such cases must always remain the opprobrium of ophthalmology. There are many cases, however, of traumatic cataract attended by rapid increase of intraocular tension, with the production of iritis on irido-cyclitis, and ultimate excavation of the optic-nerve head in which the foreign body either lodges in the lens or is withdrawn at the time of the accident.

The proposition the author desired to advance was this: In cases of traumatic cataract with rapid increase of intraocular tension, an operation should be performed, and that operation should be not linear extraction, but an extraction made with the Graefe knife, and with the incision located in the corneo-scleral junction. The knife should cut from one-third to two-fifths of the corneal circumference, according to the extent to which the softening process in the lens has advanced. If glaucomatous symptoms supervene with softening of only a small part of the lens, the corneal incision should be large. If the softening involves the whole of the lens, the incision should be of less extent. The extent of the incision in the cornea, as far as healing is concerned, is of little importance provided we make an aseptic operation. The chief merit of the operation lies in the avoidance of the valve which is produced by the linear methods. In other words, the author's method permits of free evacuation of all the lenticular substance with the least amount of traumatism. An iridectomy is not made. All *débris* is removed at once. This cannot be accomplished by the linear method. The author then reported two very instructive and interesting cases.

DR. J. H. KELLOGG, of Battle Creek, Mich., demonstrated by diagrams and illustrations the deformities of American women resulting from neglect of physical exercise and the conventional mode of dress.

DR. LEWIS C. 'CLINE, of Indianapolis, Ind., read a paper entitled

SOME OBSERVATIONS ON SORE THROAT DUE TO CONCRETIONS IN THE TONSILS.

Cases of recurring tonsillitis or sore throat often develop without any apparent cause, but are doubtless due to chronic inflammation of the follicles, altered and retained secretions. Follicular concretions predispose to attacks of quinsy, and in the author's judgment are the cause of the majority of these cases, and they can be permanently cured by carefully hunting out and destroying all the crypts and pockets in which these bodies are formed. The writer reported several interesting cases which emphasized the point that he wished to make, namely, that perverted secretion of the follicles of the tonsils from catarrhal inflammation resulting in cheesy concretions, which remain as a smouldering fire ready to be fanned into a flame by the least exposure, is the cause of more sore throats and quinsy in adults than any or all other causes combined.

FOURTH DAY. — MORNING SESSION.

DR. ROBERT C. HEFLEBOWER, of Cincinnati, read a paper on

THE REMOVAL OF THE AUDITORY OSSICLES FOR THE RELIEF OF CHRONIC DEAFNESS AND OTHER ABNORMAL CONDITIONS.

After a thorough and exhaustive review of the history of operations to relieve chronic deafness from the earliest date to the present time, the author passed to

the indications for the operation. He believes that it is indicated in deafness caused by chronic catarrhal processes, as well as headache, vertigo, tinnitus, etc., accompanying this condition, adhesions and chronic suppuration from the middle ear, especially when the ossicles are necrotic. In seven cases reported, where the operation was made to relieve either deafness or tinnitus, or both, there were good results.

In closing, the writer would draw the following conclusions from his experience with this class of ear cases:

(1) No bad results attend the excision of the malleus and the incus; but removal of the stapes is not without the most serious danger, both to life and hearing.

(2) That the removal of the malleus and incus alone is far preferable to the removal of the stapes.

(3) The operation is of extreme service in chronic suppuration in suitable cases, frequently avoiding mastoid and other serious disturbances of an equally serious nature.

(4) It should be performed in cases where there is a high perforation, or where the membrana flaccida is perforated and where the ossicles are necrotic.

(5) Tinnitus, headaches of ear origin and vertigo are relieved.

(6) In suitable cases it is invaluable for relieving deafness, whether from chronic suppuration or from chronic catarrh and sclerosis.

THE NEATEST CIRCUMCISION.

DR. BRANSFORD LEWIS, of St. Louis, detailed a new and convenient method for doing this operation, which he practises.

DR. H. C. DALTON, of St. Louis, contributed a paper on

STAB WOUNDS OF THE PERICARDIUM; RESECTION OF RIB AND SUTURE OF PERICARDIUM; RECOVERY.

DR. G. FRANK LYDSTON, of Chicago, contributed a paper entitled

REMARKS ON THE RELATION OF RESIDUAL URINE TO VESICAL IRRITATION, ESPECIALLY IN PROSTATICS.

The writer said it is generally accepted that most of the symptomatic disturbances incidental to certain chronic bladder diseases, especially in cases of prostatic enlargement, are dependent upon the accumulation of residual urine. He has long been impressed with the idea that residual urine *per se* is not as important a factor in genito-urinary irritation as is ordinarily believed. He is satisfied that in a large proportion of adult males there is always a greater or less residuum of urine remaining in the bladder after micturition. If prostatic enlargement or other obstruction attacking the mouth of the bladder develop, we have the typical accumulation of residual urine characteristic of such cases. It will then be seen that there may be at varying periods of life extreme differences in the degree of accumulation of residual urine. The author believes that the residual urine is simply an incident upon which, if taken alone, the symptoms of vesical irritation in no wise depend. Ideally perfect drainage of the *bas fond* can only be accomplished by thorough drainage from above the tube through the trigone and out of the rectum. There were certain objections to this method which the author said it was necessary to dilate upon. He simply stated as his opinion that only by some such procedure can the *bas fond* be thoroughly drained.

DR. HANAU W. LOEB, of St. Louis, reported a case of

DOUBLE NASAL ATRESIA DUE TO SMALL-POX.

He spoke of the present failures in the treatment of webbed fingers and conditions due to the deposit of scar tissue. We realize quite readily the frequent futility of the treatment for the permanent relief of cicatricial contractions and adhesions resulting from syphilitic lesions of the pharynx, palate and larynx; so that while no great skill was claimed in the management of the case reported in the paper, yet the patient's condition after a year and one-half of observation merited attention.

LAPAROTOMY FOR PELVIC DISEASES NO LONGER A NECESSITY

by DR. R. STANSBURY SUTTON, of Pittsburgh.

The assertion found in the text of this paper was founded upon the following argument: (1) We have a substitute for laparotomy in total extirpation of the uterus and appendages by the vagina, either with or without morcellement. (2) The operation has already proven to be effectual and successful by Péan, Segond, Jacobs, and others in Europe, and Henrotin, Engelmann, Sutton, Edebohls, and others in the United States. (3) Total extirpation of the uterus and appendages per vaginam gives a lower mortality than does laparotomy for the removal of the appendages alone. Morcellement of small fibroid tumors gives a lower mortality than laparotomy for the removal of similar tumors. (4) These operations by the vagina shorten the convalescence of patients, who are out of bed on the seventh day. (5) In all cases of gonorrheal, tubercular, or other infectious type of endometritis with chronic salpingitis and chronic ovaritis, a cure is not effected save by total extirpation of the uterus and appendages. The vaginal route is the best. (6) In all cases of fibroid tumors of the uterus, not reaching above or quite to the umbilicus, when the uterus must be sacrificed, total extirpation of the organ, tumor and appendages by morcellement can be best effected per vaginam. (7) Small cysts of the ovary or broad ligament, or solid tumors of the ovary can be reached and by morcellement and puncture be removed through the vault of the vagina, leaving the uterus and opposite ovary and tube intact. (8) In all cases of pyosalpinx or of multiple pus centres with coexisting solidification of the pelvic roof, total extirpation by morcellement per vaginam is the only feasible operation, and it cures the patient. (9) Total extirpation per vaginam is followed by a cure in the greatest majority of cases as compared with laparotomy. (10) The following sequelæ after laparotomy do not occur after total extirpation per vaginam: Cancer of the uterus, adenoma of the uterus, tuberculosis of the uterus, gonorrheal infection, hemorrhages of the uterus, filthy catarrhal discharges from the uterus, ventral hernia, fecal and other fistulas, the mark of a wound on the abdomen. The nerve storms subsequent to total extirpation are not as great as after laparotomy. The patient is restored to perfect health; this is not the case in more than fifty per cent. of laparotomies for pelvic diseases. (11) The bacteriology of infectious disease demands removal of the

uterus with the appendages. (12) Total extirpation per vaginam is in strict conformity to anatomical relation. (13) The physiological results following total extirpation are free from jarrings, and the patient is functionally a smoothly running mechanism. (14) Laparotomy for these diseases is followed by all manner of physiological disturbances which affect the vascular, muscular, nervous and digestive systems. (15) In the face of this argument, laparotomy for pelvic disease is no longer a necessity, but in the author's opinion should be abandoned excepting in very rare instances indeed.

Dr. Henry O. Marcy, of Boston, read an essay on

MODERN SURGICAL TECHNIQUE.

This paper first emphasizes the importance of a most careful bacteriological training on the part of him who would become proficient in surgical practice. In the preparation of the operating-room, Dr. Marcy points out the ease and safety with which an ordinary living-room, by preference the kitchen, is made comparatively sterile, when from necessity the surgeon is called upon to act promptly and suddenly. In abdominal wounds, where irrigation is not advised, he substitutes for it a slowly flowing stream of oxygen gas from a compressed cylinder. This sterile gas is heavier than atmospheric air which it displaces, and as a consequence renders the wound less likely to infections from the products of respiration and atmospheric contamination. Dr. Marcy reiterates his well-known views upon the value of tendon sutures, buried in all aseptic wounds for the approximation and reinforcement of the structures, emphasizing the importance of abandoning the drainage-tube in all aseptic wounds and hermetically sealing the same with iodoform collodion. Aseptic wounds made in aseptic structures, aseptically closed and sealed, are always followed by primary union.

The Committee appointed to consider the

RECOMMENDATIONS CONTAINED IN THE PRESIDENT'S ANNUAL ADDRESS

submitted the following report:

(1) While this Association is loyal to the last degree in its affiliations and associations with the members of the regular profession, it still believes that it is not derogatory for a scientific physician to hold a patent on a mechanical or surgical device that proves of benefit to suffering mankind. It sees no reason why the genius and talent of an inventive physician should not be protected by law as well as that of any other man.

. . . . . .

(6) This Association unites in urging upon the Congress of the United States the propriety of appropriating sufficient funds for the proper maintenance and support of a medical school at Washington, whose purpose shall be the instruction and training of physicians entering the army in regard to requirements of the practice of medicine and surgery in the military service of the United States.

(7) This Association believes that in the proper education of physicians by adequate preliminary training, and a college curriculum of four years and a final examination for license by the State, lies a true solution of many, if not all, the much controverted questions of ethics; and that at the present day a furthur agitation of these questions by debate on the floor of societies met together for scientific advancement is unwise and injudicious.

. . . . . .

The report was signed by the Chairman, Dr. William Warren Potter, and by Drs. I. N. Love, T. H. Stucky, A. S. Garnett and Chas. B. Parker.

The Committee on Nominations made the following report: President, Dr. W. N. Wishard, of Indianapolis; First Vice-President, Dr. Thomas E. Holland, of Hot Springs; Second Vice-President, Dr. Chas. B. Parker, of Cleveland; Secretary, Dr. Frederick C. Woodburn, of Indianapolis; Treasurer, Dr. Harold N. Moyer, of Chicago.

Judicial Council — Drs. W. F. Barclay, of Pittsburgh, and A. H. Meisenbach, of St. Louis.

The next meeting will be held in Detroit, in September, 1895. Chairman of Committee of Arrangements, Dr. H. O. Walker, of Detroit.

## Recent Literature.

*Recherches cliniques et thérapeutiques sur l'épilepsie, l'hystérie, l'idiotie et l'hydrocéphalie.* Compte rendu du service des enfants idiots, épileptiques et arriérés de Bicêtre pendant l'année 1893. Par Bourneville, médecin de Bicêtre, avec la collaboration de MM. Boncourt, Cornet, Leloir, Jules Noir et P. Sollier. Vol. XIV. Avec 89 figures dans le texte, et une planche. 8vo, pp. lxiii, 372. Paris: aux bureaux du *Progrès Médical*. 1894.

The annual volumes of reports from the department for idiotic, epileptic, and backward children at Bicêtre, edited by Bourneville, always contain much of interest and value, but the present volume is more important than most of its predecessors. The first part contains the usual tables, reports on a new building for the Fondation Vallée to contain a hundred beds, and notes as to therapeutic and educational measures employed. In Bicêtre and the Fondation there are over six hundred children. The second part contains clinical studies of some of the more unusual cases, with reports of autopsies, and three elaborate papers by Bourneville, Cornet, and Noir. The first paper is devoted to a study of the surgical treatment of idiots as contrasted with the medico-pedagogical. After an analysis of eighty-two craniectomies reported by different writers, and of twenty-two autopsies of idiots at Bicêtre, Bourneville shows conclusively that craniectomy does not rest upon any substantial basis. The premature synostosis of the cranial sutures, upon which Lannelongue based his theory of the operation, does not exist, and there are deep and extensive changes in the brain not amenable to surgical treatment. The results of operation are slight, whereas medico-pedagogical treatment usually gives rise to considerable amelioration. Bourneville and Cornet report thirty cases of epilepsy treated with testicular juice; in eight cases the attacks were a trifle diminished; in twenty they grew worse; there was sometimes a slight increase in weight, but there was no improvement in the mental condition. The last article, by Bourneville and Noir is an elaborate study of chronic hydrocephalus, with many pictures of the brains and skulls of the cases reported. Here, again, surgical interference is deprecated, the best results being obtained by compression, revulsives, and educational methods.

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS

## THE PATHOGENY OF DIABETES.

THE pathogeny of diabetes, long wrapped in complete obscurity, is being elucidated by the researches of many modern investigators. We have alluded in former numbers of the JOURNAL to the labors of Pavy, of Mehring and Minkowski, of Lépine and others; and to-day we call attention to the recent communications of Chauveau and Kauffmann.

In 1886 these authors published a memoir in which they showed by experiments on horses the relation of glucose production and glucose combustion to thermogenesis and muscle-work in the animal economy. They conclude as follows: "In the glands as in the muscles, the work of the organs increases the destruction of glucose proportionately to the heightened activity of the combustions of which they are the seat. Where there is but little functional activity, there is only slight augmentation of the sugar consumed. Where the work is considerable, the consumption of sugar is equally considerable."[1]

In a subsequent paper read before the Academy (December 13, 1886), they point out the rôle of the liver in calorification and muscular work, and conclude that the glycogenic processes (especially glucose formation in the liver) are the more active the more any one or more of the organs and tissues are exercised, and *vice versa*. As long as the liver furnishes glucose to the blood in sufficient amount, the animal continues to produce the quantity of heat necessary for the work of the organs and the maintenance of the bodily temperature. Let the glycogenic function become retarded and glucose disappear from the blood in the vessels, then the organic combustions languish and death takes place by arrest of calorification. It is in animals subjected to inanition that this fact becomes most apparent at the time when the depleted and exhausted organism can no longer furnish to the liver the materials which enable it to perform its function of glucose-storer and distributor.

[1] Memoires de l'Académie des Sciences, January, 1895.

In a third communication to the Académie des Sciences, February 13, 1893, the same experimenters have given the results of a series of experiments on dogs rendered hyperglycemic by lesions of the central nervous system; then of another series of subjects rendered glycosuric by extirpation of the pancreas. In all these cases the comparative analyses of the arterial and venous blood showed that the latter is always more saccharine than the former, as it is in the normal state. In fact the proportion of glucose consumed in the capillaries during the hyperglycemic and during the normal state, as shown by their estimates, is about the same and seems to justify their conclusion "that the fundamental phenomenon of the consumption of glucose in the nutritive movements is not lessened when there is hyperglycemia, nor exalted when there is hypoglycemia."

In a fourth article published in the "Bulletins" of the Academy of Sciences, March, 1893, they sum up their conclusions concerning the relation of the pancreas to sugar formation in the liver:

(1) The glycogenic function of the liver is under the control of a certain regulating mechanism.

(2) The pancreas is an important part of this mechanism, as is indicated by the experimental diabetes of Minkowski and others.

(3) The influence of the pancreas is not exerted directly on the liver, but through the medium of the nervous system.

(4) The regulating centres are: (*a*) a check centre in the bulb; (*b*) an excitatory centre in the upper cord between the bulb and the origin of the fourth pair of cervical nerves. The nerves concerned are certain *rami communicantes* of the spinal nerves to the great sympathetic.

In brief (for we must pass over many ingenious and interesting considerations advanced to establish their positions), these writers believe that the pancreas secretes a product which diminishes glucose formation in the liver and increases glucose fixation. Their hypotheses differs somewhat from that of Lépine, who thinks that this product of the pancreas is a "glycolytic ferment" which destroys glycogen in the blood. These hypotheses may or may not be true, but the fact remains that destructive lesions of the pancreas are attended by a severe and permanent glycosuria. If now (as our authors believe, and as the French school of medicine generally teaches), every form of diabetes is due to a fault in the regulating mechanism of the liver whereby glucose formation is intensified above the needs of the economy, it is hard to escape the conclusion that the pancreas has an important part in this regulation; whether by a secretion stimulating glucose fixation or inhibiting glucose formation, or by some reflex nervous influence.

In a recent number of the *Semaine Médicale*,[2] Kauffmann returns to the subject of the pathogeny of diabetes, affirming in opposition to the School of Bouchard, "that the facts compel us now to abandon entirely the theory according to which chronic diabetes is due to a diminution of the destruction of sugar in the economy." He believes that it has now been experimentally established "that diabetic hyperglycemia is always due to excess of glucose production and not

[2] January 16, 1895.

to an arrest or retardation of carbohydrate-destruction in the capillaries of the tissues."

It will thus be seen that the French pathologists are insisting with renewed emphasis on the truth of Claude Bernard's fundamental tenet as to the glycogenic function of the liver and the hepatic origin of saccharine diabetes. It is the especial function of the liver to store up glucose under the form of glycogen, and to yield it up to the blood when needed, and it is by virtue of the regulating power which this organ possesses that in health the amount of glucose in the blood never exceeds one and a fraction per 1,000 parts. There is evidence that this storage power of the liver over glucose may be exceeded by excessive ingestion of carbohydrate, and the person may be temporarily diabetic. Or a more or less permanent condition of glycosuria may be brought about by nervous influences, poisons, etc., acting on the liver and increasing glucose production. "Diabetes," says Lecorché, "is a neurosis of the liver," and its causes may be central, peripheral, or reflex. The proximate pathological condition attending it is active hyperemia of the liver.[3] He reports numerous cases; in all tumefaction of the liver was persistently noted. This view is also held by Klebs, and apparently endorsed by Senator.[4] In passive congestion, however (as in chronic disease of the heart), the diabetes generally disappears. This is also the case with cirrhosis, cancerous, fatty, and other destructive diseases of the liver, at least when the lesions are far advanced; the diabetes no longer exists.

It might almost be a matter of wonder that these destructive diseases which abolish the glycogenic function of the liver should also cause cessation of the diabetes for they certainly destroy the power of the liver to fix glucose. At first sight this might be adduced as an argument against the hepatic origin of diabetes. But there can be little power in the organism to appropriate carbohydrate material when the liver is so profoundly altered. There is a general repugnance for sweets and starches, and appetite and digestion are at a low ebb. Perhaps also in these cases, there may be a compensatory action on the part of the intestinal villi, as Pavy intimates. He believes that no sugar is assimilated by the organism that is not first intimately blended with peptone and synthetized as proteid by the protoplasm of the villi of the intestines. What escapes the villi is stored away as glycogen by the liver. The protoplasm of the villi, as well as of the hepatic cells, must first be overcome before the person can become diabetic.[5]

## THE SURGICAL TREATMENT OF GENERAL PERITONITIS.

IN a paper read before the Philadelphia Academy of Surgery (October 1, 1894), Dr. Oscar H. Allis suggested a treatment for general peritonitis as striking as it is original. He points out the necessity of obtaining permanent drainage — simple washing of the septic peritoneal cavity will, and usually does, prove inefficient. We have the problem of the removal of the pus, fibrin, and inflammatory products which in a general septic peritonitis will certainly continue to form after a single washing — a problem of the greatest difficulty — and one as yet unsolved. The best practical methods so far suggested are drainage of the bottom of the pelvis by tubes or gauze brought out through the lower end of a median incision. This method, however, though efficient in draining blood and serous effusion after laparotomy, does not afford permanent drainage in septic peritonitis, for adhesions soon form between coils of intestine, abdominal wall, etc., transforming the peritoneal cavity into a series of pus pockets, the adequate drainage of which requires that extensive adhesions be broken up, only to re-form again with rapidity. Whether continuous flushing with warm sterilized water through tubes carried to the most dependent parts of the abdomen will be efficient can only be learned by trial.

The method suggested by Dr. Allis, however, is far more radical. He proposes that a long, median incision be kept open by packing, that rubber dam covered with cerate be tucked in between the abdominal wall and the intestine to prevent adhesions, that the whole cavity as far as possible be lubricated, and that the patient be kept, except at the times of dressing, in the prone position. The doctor states that this method is pure theory; with this we would agree, and add that the theory was admixed with very little regard for mechanical, anatomical or physiological facts. In the first place it is necessary to remember that patients with general peritonitis are sick, and that the prone position is never taken by a sick patient, as it adds the weight of the vertebral column and viscera to the amount to be lifted by the muscles of respiration, at each expansion and contraction of the chest and diaphragm. It is a thoroughly uncomfortable position for a patient with severe abdominal disease, and one which would be sure to hasten a fatal termination. Our author suggests that a thin well-padded strip of wood about three feet long, strapped transversely to the pelvis, might serve to keep the patient in the prone position. The details of arranging the matter he does not go into. The wisdom of keeping a patient critically ill from lying in a comfortable position by strapping him to a stick of wood so that he cannot turn on his back, might, it would seem, admit of question.

Another objection of equal weight would seem to be the impossibility of preventing the intestines from prolapsing through this wound, and becoming spread out in an artistic tangle inside the dressing. Every surgeon knows by experience what care is required to prevent intestine, if not adherent to the edges, from prolapsing through a long, unsutured wound, even with the patient on the back, especially if there is a slight cough. Dr. Allis must be a skilful dresser, if

[3] Etudes Médicales, p. 20.
[4] Ziemssen's Cyclopædia, vol. xvi.
[5] Physiology of the Carbohydrates, London; See also Boston Medical and Surgical Journal, August 23, 1894, p. 197.

he is able to keep intestines from slipping outside the abdominal wall against gravity as well as grease. It would, in our belief, be impossible to adjust so tight a binder as to prevent this untoward result.

Dependent drainage is undoubtedly what is wanted; but we should certainly confine our efforts to methods which would not be almost certain to kill the patient. Dependent drainage by incision in either flank, added to drainage of the pelvis, would according to our present knowledge be far preferable to Dr. Allis's theoretical method. If he ever puts his method in practice, we hope he will report his results.

## CASTRATION FOR HYPERTROPHY OF THE PROSTATE.

RELIEF from the distressing symptoms caused by prostatic hypertrophy has long been a surgical desideratum. A very large proportion of men who attain to the age of fifty-five and over, instead of spending the last years of their life in active pursuits, or rest and recreation earned by a well-spent life, are rendered thoroughly miserable from the effects of enlargement of this gland, and compelled to give a large part of their time and attention to the care of their urinary apparatus. There have, heretofore, been for these unfortunates but two alternatives: one, the temporary relief afforded by catheterization, necessarily continued for the remainder of life, and almost always bringing sooner or later infection of the bladder, with all its attendant and sequent results, which finally, after a time of gradually increasing misery carry off the patient; the other, prostatectomy, either suprapubic or perineal, promising at the risk of a formidable and dangerous operation, relief which is perhaps only temporary. Often on account of the dread of the operation it has been put off till cystitis, pyelitis, etc., have almost worn out the patient, and gained so firm a hold that the operation is either fatal, or fails to give relief.

Of late years, the observation that animals — dogs, sheep, calves, etc. — castrated when young have no prostates or only rudimentary ones, has led to experiments on animals, performed in this country by White, of Philadelphia, which have shown that castration causes atrophy of the prostate. If this operation could be applied to man, so as to diminish the size of an hypertrophied prostate, it was recognized that it would have obvious advantages over the old operation of prostatectomy. With modern aseptic methods the operation is almost devoid of danger. It is very easy and simple of performance. The only disadvantage attached to it is a sentimental one, which it would seem ought to have little weight in comparison with the severity and danger of the symptoms it is designed to relieve.

The first surgeon to perform the operation was Ramm, of Christiania, who in 1893 did two castrations for hypertrophy of the prostate. Since then it has been performed by Mansell-Moullin, in England, White, Ricketts, and others in this country; in all, thirteen cases have been reported. Other operations have been performed, but not yet published. In the reported cases the results have been almost uniformly favorable. Some men, previously obliged to lead a "catheter life," have been enabled by the operation to dispense with catheterization, others have been obliged to resort to the catheter much less frequently, and have not had to get up at night. An actual diminution in the size of the prostate has been noted.

A striking point about these cases is the short interval after the operation at which improvement begins. Greater ease of urination has been noted as early as the second day.

In view of the inherent objections of patients to castration, the operation of the division of the vas deferens has been suggested and tried, but we are informed with less satisfactory results.

As stated above, the suffering from the results of enlarged prostate is so severe, that sufferers might easily consent to lose testicles, or almost any other organ of their body, if relief were promised without serious danger. It is probable, in view of what has been already done, that cases will continue to be reported in the near future. The results will be awaited with interest.

## MEDICAL NOTES.

THE GERMAN CONGRESS OF INTERNAL MEDICINE will be held this year at Munich from the 2d to the 5th day of April. Professor von Ziemssen will preside.

A STATE EXAMINATION IN GEORGIA.—The new law providing for a State board of medical examiners (really, three boards — regular, homeopathic, and eclectic), went into effect on January 1st.

A PUGILIST IN A NEW RÔLE.— "The Medical Department of Vanderbilt University recently distinguished itself by inviting pugilist James Corbett to lecture to its students on physical culture. Even astonished comment pales before the shameful fact."— *Medical Record.*

JOURNAL OF THE AMERICAN PUBLIC HEALTH ASSOCIATION.— No. 1, Volume 1, of this journal, published quarterly, has appeared. It is a handsome and well-printed periodical. The papers in this issue comprise the larger proportion of those read at the Montreal meeting.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY. — At the annual meeting of the Harvard Medical Society held January 26th, at Harvard House, the following officers were elected for 1895: President, Dillon Brown, M.D.; Vice-President, Charles L. Gibson, M.D.; Secretary, Theodore Dunham, M.D.; Treasurer, George E. Brewer, M.D.

THE DIAGNOSIS OF DIPHTHERIA IN PHILADELPHIA. — The Laboratory of Bacteriology of the Philadelphia Polyclinic is ready to undertake this examination and to report to physicians the bacteriologic

diagnosis of suspected cases, thus offering to perform for Philadelphia the same office which the Bacteriological Laboratory of the Harvard Medical School does for Boston.

CIGARETTE ROLLER'S CRAMP.— According to the *Medical Press*, "cigarette roller's cramp" must now be added to the list of acquired professional paralyses. Both in Spain and France it is said to be very prevalent. Intense pain in the joints of the hands and fingers of the workers, who are girls, supervene, and there is often inability for some time to approximate the thumb and index finger.

THE ANTITOXIN TREATMENT IN FRANCE.— The sum voted by the French Legislature for the carrying out of the antitoxin treatment was 100,000 francs. It is intended to make a grant in aid of the antitoxin treatment a permanent item in the French budget. In the estimates for 1895 appears a subvention of 80,000 francs to the Pasteur Institute for the preparation of antitoxin, together with one of 20,000 francs for the general purposes of the inoculation service.

COLOR BLINDNESS AMONG ASIATICS. — Among the publications of the German Asiatic Society of Tokyo, Japan, for 1894, is a paper by Dr. F. B. Stephenson, U. S. N., under the title of "Color Blindness in Asiatics," giving the result of observations among the natives of Hawaii, Unalaska (Aleutian Islands), Japan, China, Annam, Siam, including the mixed nationalities from Borneo and India, which inhabit Singapore and other parts of the peninsula of Malacca. It appears that none of these races are free from defective color sense.

A CASE OF LONGEVITY.— According to the *Lyon Médicale* there has just died at Saratov, Russia, at the age of 125½ years, a veteran of the campaigns of Napoleon I. This remarkable personage, Lieutenant Nicolas Savin by name, was born in Paris in 1768, enlisted in a regiment of huzzars in 1798, and took part in the most important campaigns of the Consulate and the Empire. Having been taken prisoner by the Cossacks during the retreat from Beresina, Savin took up his residence, eighty-two years ago, at Saratov, where he was married, and lived during the last years with his eighty-two-year-old daughter. In 1887 the Czar Alexander III, made the old soldier a present of a thousand roubles.

DEATH FROM A GLOVE FIGHT.— A sparring accident is reported from London in which death followed an unusual chain of events. The victim of the accident was disabled in the second round of a glove contest by a blow on the jaw. At King's College Hospital he was found to have a fractured right jaw, for which he was treated. Seventeen days later, a second fracture was found at the angle of the left jaw, in connection with a foul abscess cavity. Deceased died of septic pneumonia. The gloves used in the fight were said to have weighed six and one quarter ounces. This appears to have been a contest for money with all the characteristics of a prize fight, save that light gloves were used. From the medical evidence both fractures were caused by the same blow, and the undetected second one was rendered septic by contact with the fangs of a decayed tooth. The spleen contained an infarct about the size of a hen's egg, which was breaking into an abscess.

PROFESSOR WIDERHOFER ON THE ANTITOXIN TREATMENT. — In summing up his paper on serum therapeutics at the St. Ann's Hospital in Vienna, a brief *résumé* of which was given in the JOURNAL for January 17th, Professor Widerhofer makes the following statement: "To my mind there does not remain the slightest doubt that Behring's *Heilserum* influences certain classes of diphtheria cases, and not the mildest forms either, so favorably that Behring's serum therapy deserves the name of a specific remedy against diphtheria, with which no other so far discovered deserves comparison." A consideration of his cases also fully confirms the statement of Behring that, "when postponed till after the third or fourth day of the disease, the effect of the antitoxin will be doubtful." This statement, however, does not mean that it is not worth while to try the serum treatment in these cases. *Apropos* of these statements and certain others which have been omitted from lack of space, the author says: "With regard to these points my mind is made up. What I have written I have seen, and what I have seen I believe. Therefore I fear no contradiction." The article, as a whole, is thorough, careful, and bears evidence of an honest and critical study of the facts. It will well repay perusal in the original.

## BOSTON AND NEW ENGLAND.

THE PRODUCTION OF ANTITOXIN FOR BOSTON.— Five horses were inoculated with diphtheria toxin at Gallop's Island on January 25th, as a first step toward the production of antitoxin by the Boston Board of Health.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, January 30, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 69, scarlet fever 54, measles 58, typhoid fever 10.

BOSTON CITY HOSPITAL CLUB.—The annual dinner of the City Hospital Club will be held at Young's Hotel on the evening of Wednesday, February 6th, at 6 o'clock. The annual meeting, postponed from June last, will precede the dinner, and will be held in the reception rooms provided for the Club, at 5.30 o'clock.

THE DANGERS OF A LINEMAN'S EXISTENCE.— The spectacle of a man hanging apparently lifeless from the top of an electric-light pole on Cambridge Street, Boston, on November 26th, must have reminded those who saw it of the danger to life, which at present attends the business of a lineman for electric light and power companies, unless constant caution is exercised. It is only a short time since a man was burned to

death at the top of a pole on Congress Street, while another who went to his assistance received the shock of the current, fell, and fatally fractured his skull.

NEW YORK.

APPOINTMENTS TO CITY BOARD OF HEALTH.— At a meeting of the Board of Health held January 24th, the following appointments were made: Assistant chemist, James H. Miller; assistant bacteriologists, Drs. Alexander Lambert, C. B. Fitzpatrick, A. M. Williams, and John S. Billings; assistant pathologist, Dr. George P. Biggs. These appointments were made from over thirty applicants, who were required to pass a civil-service examination, and the field of duty of the new officials will be in the Board of Health's antitoxin laboratory. The salary of each is $1,200 per annum.

MORTALITY.— During the week ending January 27th there were reported 933 deaths, of which 62 were attributed to influenza. In the week ending January 20th the number of deaths was 949, with 79 from influenza.

FIRE AT THE COLLEGE OF PHYSICIANS AND SURGEONS.— Fire was discovered on Sunday morning, January 27th, in the flooring between the second and third stories of the College of Physicians and Surgeons. The alarm was promptly given, the flooring was cut away, and the portion of the building in which the fire occurred was deluged with water. A number of pathological specimens in the museum were damaged, and the total loss from fire and water is estimated at $10,000. The cause of the fire is unknown.

## Miscellany.

### RESOLUTIONS ON THE DEATH OF DR. A. L. LOOMIS.

UNIVERSITY OF THE CITY OF NEW YORK.
January 25, 1895.

AT a meeting of the faculty held this day the following preamble and resolutions were adopted:

*Whereas*, In the wisdom of Almighty God it has been decreed to remove from among us our esteemed and honored associate, Dr. Alfred L. Loomis, who has been for thirty-three years identified with the progress and development of the Medical Department of the University of the City of New York, and to whose untiring energy and zeal that institution largely owes its present high position, we, the members of its faculty, hereby

*Resolve*, That in the death of Dr. Loomis we have met with an irreparable loss, in one whom we have ever valued as a friend, respected for his judgment and wise counsel, and admired for his strength and firmness of character, for his professional skill, his scientific learning and his literary attainments; that, while overcome with a sense of personal bereavement, we are not unmindful that the medical profession throughout the country has lost its foremost leader and the public a distinguished citizen.

And be it further

*Resolved*, That this resolution be spread upon the minutes of this meeting, and that a copy be suitably engrossed and sent to the family of Dr. Loomis in token of our profound sympathy and sorrow. CHAS. INSLEE PARDEE, *Dean*.

### OBITUARY. — A. L. LOOMIS, M.D., LL.D.

DR. A. L. LOOMIS died in New York of pneumonia, Wednesday, January 23d, after a very short illness. He was ill less than four days.

Dr. Loomis was born in Bennington, Vt., in 1831. He was graduated at Union College in 1851. Soon after graduating he went to New York and studied medicine under Dr. Willard Parker. In 1853 he took his medical degree at the College of Physicians and Surgeons. He served as an interne for two years at the charity hospitals on Ward's and Blackwell's Islands. He then began general practice in New York.

He was appointed visiting physician to Bellevue Hospital in 1859, and retained that position until his death. He was visiting physician to the Charity Hospital on Blackwell's Island from 1860 to 1875 and to Mount Sinai Hospital from 1870 to 1880.

He was lecturer on physical diagnosis in the College of Physicians and Surgeons from 1862 to 1865, and was then made adjunct professor of the theory and practice of medicine in the University of the City of New York. He was appointed professor of pathology and practice of medicine in the same institution in 1867, and held that chair until his death. The degree of LL.D. was given him by this University.

A friend of the University gave $100,000 to the medical department through Dr. Loomis in 1886 for the purpose of building and equipping the laboratory known as the Loomis Laboratory in East Twenty-sixth Street.

Dr. Loomis was a member of the principal local and national medical societies. He had been President of the Medical Society of the State of New York, of the New York Pathological Society, the New York Academy of Medicine, the New York County Medical Society, the American Climatological Society, the Association of American Physicians.

He was at the time of his death consulting physician to the Charity Hospital, Mount Sinai Hospital, the Hospital for the Ruptured and Crippled, the New York City Asylum for the Insane, and the Northern, Northwestern, and De Milt Dispensaries, and the Out-door Poor Department of Bellevue Hospital.

He wrote a number of books on medical subjects well-known and much used as text-books, among the principal of which were: "Lessons in Physical Diagnosis," ten editions between 1872–1893; "Diseases of the Respiratory Organs, Heart and Kidneys," 1875; "A Text-Book of Practical Medicine," 1884.

It is as a practitioner rather than as a writer or scientific student that his reputation will stand. He thoroughly understood the practice of medicine, and inspired much confidence in patients. He was greatly in demand as a consultant, and his income from his practice is said to have been very large. He was an excellent man of affairs, and this gift enabled him to be of much service as its President to the New York Academy of Medicine.

His place in the profession will not be easily filled.

## Correspondence.

### ETHICS OF THE METROPOLITAN SURGEON AND THE METROPOLITAN HOSPITAL.

HAVERHILL, MASS., January 23, 1895.

MR. EDITOR: — Have you room in your valuable journal for the following wail? And can you, out of the richness of your experience, suggest anything to help us?

It appears that the Massachusetts General Hospital, and, to a less extent, the other hospitals of Boston, are being conducted in a manner prejudicial to the interests of many members of the medical profession in this State.

We have, for instance, a patient who needs and desires a certain operation. Having "taken lessons" from the

distinguished surgeons of Boston, New York, Philadelphia; some of us also from the distinguished authorities in foreign lands; having had years of practice and a considerable record of cases operated upon with about the usual percentage of success which our teachers have had, we have no hesitancy in assuring our patient of our willingness to undertake the surgical care of his case. Now comes the question of fee. We offer our services for somewhat less than the metropolitan surgeon's charge, always with the mental protest that we really ought to have as much when we render the same service and are as successful. What then often happens? Our patient finds in some way that he or she can go to the Massachusetts General Hospital and get the treatment absolutely free, so far as the surgeon's fee is concerned. This fee we cannot compete with and we respectfully submit that we are grievously injured thereby.

This is bad enough; but, Mr. Editor, I was lately shown a letter received by a patient of this kind from one of the surgeons to the Massachusetts General Hospital wherein he confides to the patient, *my* patient, that in his opinion there is no medical man in my town sufficiently competent to treat her case surgically, and advising her to come to him. This is worse.

Will you kindly put yourself in my place for a moment, or will the surgeon referred to put himself in my place, and see if there is not just cause for complaint?

A fellow-practitioner, a fellow-member of the State Society, feels so desirous of securing my business that he is impelled to cast reflections upon my professional attainments in order to obtain it. I would like just here to say that this gentleman is not acquainted with me, or he would know better than to subscribe his name to such a statement, and that he appears to want a case much more than the honorable gentlemen of our noble profession should. This is our wail, Mr. Editor. Is there any help for us?

Is it necessary that the Massachusetts General Hospital should treat cases for nothing, when they are able to pay us a fair fee?

Must we continue to subsist upon the exquisite enjoyment of the fame which our metropolitan brothers get from patients who would give us some money and some reputation? And is it true charity, is it broadly ethical to pauperize these people and lower the standard of the medical profession outside of the city of Boston? S.

[Plain justice demands the publication of our correspondent's cry for light and help in a perplexity and distress which has troubled others besides himself. He asks questions which he has a right to ask, if asked, as his are, in a straight and manly fashion. They are, however, easier asked than answered. The golden rule is a simple, good and safe rule for all, whether of the profession or not. As to the line at which gratuitous hospital relief should be drawn, it is neither easy to fix it theoretically nor to enforce it practically. That many and grave abuses exist at present cannot be denied: abuses which work an injury to the public, and a wrong to many of the profession — to those holding hospital appointments as well as to those who do not. Some change will follow the increase of local hospitals; the right to charge fees at the metropolitan hospitals is a problem which has received much attention from trustees and from medical staffs, and much has been adduced both for and against the granting of such a right. Perhaps there are those who have information and opinions which would give some satisfaction to our correspondent in his perplexity. It is not an unknown thing that a practitioner in a small town or in the country should arrange with a *metropolitan* surgeon to take *all* his surgery — that which pays and that which does not. Is this ethical? There are other questions which might be asked; but we have already confessed it is easier to ask than to answer. — ED.]

## "FOR THIS RELIEF MUCH THANKS."

AVON RANCH, WYOMING, Jan. 2, 1895.

MR. EDITOR: Did Edward Courtenay, Earl of Devonshire, ever have his seminal vesicles stripped by a medico? Is his epitaph to be interpreted as an argument *pro* or *con* the practice?

> "What we gave, we have,
> What we spent, we had:
> What we left, we lost."[1]

Dr. Fuller Seed (an enthusiastic student and ardent admirer of Shakespeare), whom I met at round-up last week, quoted to me a passage in which he claims that the immortal William refers (prophetically) to this burning topic:

> "But man, proud man,
> Drest in a little brief authority,
> Most ignorant of what he's most assured,
> His glassy essence — like an angry ape,
> Plays such fantastic tricks, etc."

Yours in perplexity, MAVERICK.

[1] Geneological History of the family of Courtenay, p. 142.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JANUARY 19, 1895

| Cities. | Estimated population. | Reported deaths in each. | Deaths under five years. | Percentage of deaths from Infectious diseases. | Acute lung diseases. | Typhoid fever. | Diphtheria and croup. | Scarlet fever. |
|---|---|---|---|---|---|---|---|---|
| New York | 1,956,000 | 949 | 308 | 9.90 | 24.97 | .22 | 4.95 | 1.87 |
| Chicago | 1,660,000 | — | — | — | — | — | — | — |
| Philadelphia | 1,139,457 | 412 | 173 | 11.55 | 18.10 | 2.10 | 6.72 | .42 |
| Brooklyn | 1,043,000 | 508 | 142 | 10.80 | 25.40 | .80 | 8.20 | — |
| St. Louis | 540,800 | — | — | — | — | — | — | — |
| Boston | 501,107 | 191 | 64 | 9.36 | 22.88 | — | 5.72 | 2.60 |
| Baltimore | 500,000 | — | — | — | — | — | — | — |
| Washington | 285,000 | 110 | 31 | 4.55 | 7.28 | .91 | — | — |

| Malden | 30,209 | — | — | — | — | — | — | — |
| Chelsea | 29,806 | 14 | 2 | 14.28 | 14.28 | — | 7.14 | — |
| Fitchburg | 29,393 | 12 | 3 | 16.66 | — | — | 8.33 | — |
| Newton | 28,837 | 7 | 1 | — | 14.28 | — | — | — |
| Gloucester | 27,293 | — | — | — | — | — | — | — |
| Taunton | 26,564 | 7 | 4 | 42.84 | — | — | 42.84 | — |
| Waltham | 22,038 | 0 | 0 | — | — | — | — | — |
| Quincy | 19,642 | — | — | — | — | — | — | — |
| Pittsfield | 18,802 | 4 | 0 | — | — | — | — | — |
| Everett | 16,585 | 4 | 2 | 25.00 | 25.00 | — | 25.00 | — |
| Northampton | 16,331 | 3 | 2 | — | — | — | — | — |
| Newburyport | 14,073 | 4 | 2 | 25.00 | 25.00 | — | — | — |
| Amesbury | 10,920 | 2 | 2 | — | — | — | — | — |

Deaths reported 2,940: under five years of age 831; principal infectious diseases (scarlet fever, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 314, acute lung diseases 949, consumption 526, diphtheria and croup 156, scarlet fever 47, typhoid fever 38, diarheal diseases 21, measles 16, cerebro-spinal meningitis and whooping-cough 13 each, erysipelas 7, malarial fever 2, small-pox 1.

From diarrheal diseases Philadelphia 7, New York 4, Brooklyn and Cincinnati 3 each, Cleveland, Charleston, Fitchburg and Newburyport 1 each. From measles New York 9, Philadelphia 3, Brooklyn 2, Washington and Cambridge 1 each. From cerebro-spinal meningitis Worcester 3, New York, Lowell and Somerville 2 each, Washington, Cambridge, New Bedford and Chelsea 1 each. From whooping-cough New York 8, Philadelphia, Brooklyn, Boston and Cambridge 1 each. From erysipelas Brooklyn 3, New York 2, Boston and Haverhill 1 each. From malarial fever Washington 2. From small-pox New York 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530, for the week ending January 12th, the death-rate was 20.1. Deaths reported 4,091: acute diseases of the respiratory organs (London) 389, measles 109, whooping-cough 68, diphtheria 66, diarrhea 45, fever 39, scarlet fever 33, small-pox (Liverpool) 3.

The death-rates ranged from 14.6 in Derby to 28.9 in Liverpool; Birmingham 18.4, Bradford 16.8, Croydon 16.8, Hull 18.5, Leeds 22.3, Leicester 16.9, London 19.3, Manchester 23.9, Newcastle-on-Tyne 22.7, Nottingham 20.2, Plymouth 18.7, Portsmouth 21.5, Sheffield 18.6, Swansea 18.3, WestHam 20.3.

## METEOROLOGICAL RECORD.

For the week ending January 19th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer | Thermometer. | | | Relative humidity. | | Direction of wind. | | Velocity of wind. | | Weather. | | Rainfall in inches. |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 19, 1895, TO JANUARY 25, 1895.

Leave of absence for twenty-one days, to take effect upon being relieved from duty at Fort Warren, Massachusetts, is granted CAPTAIN EDWARD R. MORRIS, assistant surgeon.

FIRST-LIEUT. ASHTON B. HEYL, assistant surgeon, is relieved from duty at Columbus Barracks, Ohio, and ordered to Fort Thomas, Kentucky, for duty.

MAJOR JOHN V. LAUDERDALE, surgeon, will be relieved from duty in the Department of the East, to take effect upon the expiration of his present leave of absence and will then report for duty at Fort Omaha, Nebraska.

LIEUT.-COL. HENRY R. TILTON, deputy surgeon-general, is relieved from duty at Fort Omaha, Nebraska, and will report in person to the commanding general, Department of Dakota, for duty as medical director of that Department, relieving COLONEL CHARLES C. BYRNE, assistant surgeon-general.

COLONEL BYRNE, on being thus relieved, will report to the commanding general, Department of the East, for duty as medical director of that Department.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 26, 1895.

O. D. NORTON, passed assistant surgeon, ordered to Naval Laboratory and Department of Instruction, Brooklyn, N. Y.

T. A. BERRYHILL, passed assistant surgeon, detached from Naval Laboratory and Department of Instruction and ordered to the Naval Hospital, Brooklyn, N. Y.

J. S. HOPE, assistant surgeon, ordered to examination preliminary to promotion, March 4, 1895.

## HARVARD MEDICAL SCHOOL.

### EVENING LECTURES.

The next lecture will be given on Thursday evening, February 7th, at 8 o'clock, by Dr. F. H. Davenport. Subject, "The Disorders of Menstruation." Physicians are cordially invited.

### SPECIAL NOTICE.

Dr. Ernst having been unable to give his lecture on "Tuberculosis" last week, will give it on Thursday evening, March 21st, at the end of the already announced course of lectures.

## SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday evening, February 4th, at 8 o'clock.

Dr. F. M. Briggs will exhibit a new Self-Retaining Drainage Canula.

Dr. F. S. Watson will read on "Castration for Hypertrophied Prostate." Discussion opened by Dr. A. T. Cabot.

Dr. George H. Monks on "The Muscles of Expression." Discussion opened by Dr. Thomas Dwight.

JAMES G. MUMFORD, M.D., *Secretary*.

THE SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION.—The Surgical Section of the Suffolk District Medical Society will hold its regular monthly meeting at 19 Boylston Place, on Wednesday evening, February 6, 1895, at 8 o'clock.

The subject of discussion will be "The Treatment of Trigeminal Neuralgia." Dr. Louis M. Tiffany, of Baltimore, Md., will open the discussion by a paper entitled "The Treatment of Trigeminal Neuralgia by Intracranial Neurectomy," followed by Dr. N. P. Dandridge, of Cincinnati, O., who will read a paper entitled "Rose's Operation for the Removal of the Gasserian Ganglion."

C. L. SCUDDER, M.D., *Secretary*, 1 Marlboro Street.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.—A stated meeting of the Society will be held on Wednesday, February 6, 1895, at 12.30 P. M., in the hall at 19 Bolyston Place, Boston.

The following papers will be read: "A Case of Criminal Abortion Presenting Some Unusual Features," Dr. W. S. Birge, of Provincetown.

"The Post-Mortem Signs of Drowning," by Dr. G. DeN. Hough, of New Bedford.

"The Murder of James Farrer," by Dr. J. A. Mead, of Watertown.

F. W. DRAPER, M.D., *Recording Secretary*.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.—The annual meeting of the Society will be held at the City Hall, Albany, commencing at 9.15 A. M., February 5, 1895, and continuing in session until 1 P. M., February 7th.

The Committee on Credentials will be at the Kenmore Hotel, Monday evening, February 4th, and members and delegates, so far as possible, are requested to register there.

WENDELL C. PHILLIPS, *Chairman Business Committee*, 350 Madison Avenue, New York City.

NEW YORK STATE MEDICAL ASSOCIATION, FIFTH DISTRICT BRANCH.—The eleventh annual meeting will be held in Brooklyn on Tuesday, May 28, 1895. All Fellows desiring to read papers will please notify the Secretary.

AUSTIN FLINT, M.D., *President*.
E. H. SQUIBB, M.D., *Secretary*, P. O. box 760, Brooklyn, N. Y.

# Address.

## ADDRESS AT DEDICATORY EXERCISES OF THE FREE HOSPITAL FOR WOMEN.

BOSTON, JANUARY 1, 1895.

BY W. H. BAKER, M.D.

IT seems appropriate on this occasion, which marks an era in our hospital life, to review the work of the past nineteen years, with a view to establish in our minds what has been accomplished by our efforts, as well as to serve as a guide to direct us in the larger field of work upon which we have now entered. We began in the small house No. 16 East Springfield Street, with a capacity for the treatment of five patients. We were able within two years to increase the number of patients to fifteen, because the financial aid of our early friends supplied us with the necessary means.

But in 1877 we had outgrown these accommodations and moved to the larger house No. 60 East Springfield Street, where we very soon increased our number of resident patients to twenty. Two years later the Out-Patient Department was established, and we became again crowded for room, when the adjoining house was added to the hospital. The growth of the work during these years is well shown by the fact that during the first two or three of them, one surgeon was able to attend to all the active work of the hospital. Of late, fourteen surgeons and physicians have been in constant attendance throughout the hospital year.

The adaptation of the principles of asepsis to gynecological surgery wrought a great change in the work of our hospital. It became more essentially a surgical institution; and under the influence of this method of treatment, we find that the number of operations quadrupled. The safety in the performance of this work offered the patient a more speedy relief with less risk than by the older methods. This fact is conclusively shown, when we consider that our capacity of twenty beds has not changed in the past fifteen years, yet the number of patients admitted and treated during that time doubled, and this without the death-rate increasing. The whole number of patients treated in the wards of our institution since its organization has been 2,309, while in the out-patient department in fifteen years there has been 46,655.

Although these figures would seem to justly indicate a cause for encouragement in our work for the relief of suffering, yet it is really but a small part of the work accomplished. I refer to the extension of knowledge in the special class of disease treated which has resulted from it. Take, for instance, the young men who have served us in the capacity of house-surgeons. Of these, two are acknowledged leaders in the department of diseases of women in New York City, having services in the Woman's Hospital, the Cancer Hospital and the Maternity Hospital. One is at the head of a hospital for women in Denver, Colo. One organized and presides over the department of gynecology in the hospital at Grand Rapids, Mich. Another established and is doing an excellent work in a hospital for women in Detroit, Mich. Still another has lately started a hospital for the treatment of women in Providence, and is attached to the staff of the Rhode Island Hospital. Three others have services in the department for women in general hospitals in this city. Thus, when we think of the hundreds of women who are being relieved at their hands and add to these the thousands that are relieved by the great number of physicians who have been instructed in this department in this institution, we can begin to realize the amount of good accomplished by the hospital as an educational organization.

The hospital, born in 1875, has already passed through the trying ordeal of youthful existence, and will obtain its majority this coming year. May we not expect that in the next decade the full strength of its manhood will be established, and the success which has crowned our labors in the past not only be continued but increased in a manifold degree? We cannot, however, imagine our work ever passing into a worthless dotage, for the ever-present call to relieve poor suffering women is constantly before us. Our best and most zealous effort will ever be demanded to meet this necessity.

As we look about us to-day and see the faces of those who have grown familiar in the unity of our work, we miss from our number some that we had hoped would be with us on this occasion. We mourn the wise counsel of Dr. Storer and the skilled touch of Dr. Strong in the active work of the hospital. But even this sorrow is turned to joy as we recall the good work for which they labored, for which we still labor, and for which others will continue to labor who succeed us. For we are united with them in carrying on this great work of relieving the suffering of the sick, of extending hope and courage to the poor, and giving of our abundance to the needy, and so fulfilling this great and noble purpose of life.

# Original Articles.

## ON SOME OF THE CLINICAL FEATURES OF PRIMARY TUBERCULOSIS OF THE GENITO-URINARY ORGANS.[1]

BY FRANCIS S. WATSON, M.D., BOSTON.

THIS communication does not aim at treating the subject at all completely, but is intended merely to call attention to some of the more suggestive symptoms of this disease as it occurs in the urinary organs, and especially as it affects the bladder and kidneys, and is prompted by the belief that the disease is frequently overlooked. I have recently asked six or eight general practitioners of fifteen or twenty years' standing, with opportunities for wide observation, how often they had seen cases of primary tuberculosis of the urinary organs. The answers varied from "four or five times," to "practically never." In some cases I have been asked to see, in consultation, patients with "obstinate cystitis," which have proved to be examples of tuberculosis, generally renal, which had not been suspected.

Since reporting a case of tuberculosis of the kidneys and bladder, and showing the specimens obtained at the autopsy, at a meeting of this Society six years ago, I have had twenty others, in which the nature of the disease was demonstrated by autopsies, or by the discovery during life of the characteristic bacilli, and four or five more which although such proof was

[1] Read before the Suffolk District Medical Society, April 26, 1894.

lacking, I am convinced were also examples of tuberculosis. In all but two of these cases the disease, so far as could be determined, originated in some part of the genito-urinary tract, as follows: in seven cases the disease originated in the epididymis; in four in the prostate or seminal vesicles; in three in the kidney; in the remainder the origin was undetermined. In two cases the autopsies showed apparently that the disease was confined to the genito-urinary tract. In two it was doubtful whether the disease had not originated in other organs, with this exception the evidence was wholly in favor of its being primary in the genito-urinary organs. One case of tuberculous epididymitis, and one of prostatitis started in gonorrheal inflammation.

Fifteen of the cases were males; six were females. The oldest patient was a man fifty years of age at the time of his death, in whom symptoms referable to the prostate and bladder, were first noticed two years' before. The youngest patient was a girl six years of age, in whom the disease was primary in the kidney, probably the first symptoms (irritable bladder and pyuria) being noted two years ago; this patient has been subjected to a right-sided nephrotomy, and is still alive.

The average duration of life after the appearance of the first symptoms which indicated that the kidneys or bladder were involved, was a little more than three years. There are two patients, one a man and one a woman, in whom the disease seems to have been arrested, one having been almost free from symptoms for two years, and the other for nearly four years. The urine of both, however, still contains a few blood-globules and from time to time a small quantity of pus. Tubercle bacilli were found in the urine of both patients; no examinations have been made for them recently. Both patients appear to be in excellent health, and are free from all subjective symptoms.

It is not probable that this series of cases represents more than a small proportion of those occurring in this neighborhood.

Perhaps the reason, that more than any other leads genito-urinary tuberculosis to be overlooked, is the readiness to rest content with a diagnosis of "idiopathic cystitis" in cases in which pyuria and irritable bladder are the conspicuous symptoms, and in which a few microscopic examinations of the urinary sediment fail to show casts, renal epithelium, or crystals, the latter fact being often assumed, under these circumstances, to free the kidneys from suspicion of being involved. "Idiopathic cystitis" in the sense of a spontaneously occurring inflammation of the mucous membrane of the bladder — an inflammation without a well-defined cause, that is to say — I do not believe exists. If inquiry is pushed far enough, some conditions of which such as the following are the most familiar examples, will be found to have originated the trouble: gonorrhœa; stone; lithiasis; stricture; prostatic hyperthrophy, and its consequences; the use of instruments; acute overdistention of the bladder, such as occurs sometimes in childbirth, or by voluntary effort, as with the insane; profound narcosis from opium or alcohol; the injestion of certain irritating drugs, for example, cantharides; in connection with certain diseases of the spinal cord, etc.

If, in the absence of these or other well-defined causes, a patient has symptoms of cystitis, it is strongly suggestive of tuberculous disease in the genito-urinary tract, probably located in the kidneys, the prostate, the seminal vesicles, or possibly in the bladder itself; but this is thought to be rarely the starting-point of the disease.

It should be borne in mind that bladder irritability is sometimes the most conspicuous sign of certain conditions in the kidney, the bladder itself being at the time free from disease. This is notably true of calculous pyelitis, of malignant and of tuberculous disease of the kidney. It is also seen in connection with simple, and more markedly with tuberculous, inflammation of the seminal vesicles and the prostate.

With regard to the method of entrance of tubercle bacilli and their lodgement in the genito-urinary tract, I will not speak, but merely note that the disease may take any of its organs as a starting-point, and that in the majority of cases in the male it begins in the epididymis, testis or prostate, and ascends more or less rapidly to the other organs. It rarely begins in the bladder; more frequently than in the latter in the kidneys, and descends.

The disease may remain localized in the epididymis or testis for a long time (several years), but it is more usual for the extension to take place more rapidly; and in some cases its progress is very rapid.

To return to symptoms. The presence of a hard lump in one epididymis, especially if the patient has never had gonorrhea or received an injury, is suggestive of its being of tuberculous nature,[2] this suspicion is heightened if the urinary sediment contains, pretty constantly, blood-globules, and is further increased if there is irritability of the bladder.

An outline of the following case will serve as an example. Four years ago a young man consulted me for a slightly increased frequency of urination and a "teasing" desire to urinate often. This had begun two months before, and had very gradually increased. The physical examination showed nothing except a hard lump in the right epididymis — this the patient had never noticed. The urine contained a very faint trace of albumin constantly, and there were always a few blood-globules in the sediment. I think the patient's statement that he had never had any venereal disease or received any injury to the parts, was true. He subsequently developed tuberculosis of the prostate, bladder and kidneys, and died.

Bryson has called attention to the existence of small, shot-like bodies to be felt in the hilus of the testis as the first evidence of tuberculous deposit in these organs. They pass unnoticed by the patient, and often by the physician.

Induration of the seminal vesicles and an uneven, furrowed prostate, or small areas of softening and indistinct fluctuation in the prostate, can often be felt by rectal examination when the disease occupies these organs. Cabot calls attention to the presence of hard, pea-like bodies to be felt in the prostate by rectal examination, in some cases as being suggestive of tuberculosis in that organ.

These features are dwelt on in order to emphasize the importance of systematic examination of the epididymes, testes, seminal vesicles and prostate in every case.

Blood in the urine is often the first sign of the disease. It is generally seen in the form of small

[2] As has been noted by Guyon and others, tuberculous disease seems not infrequently to grow out of an attack of gonorrhea. An induration in the epididymis is, however, less significant after a clap, than where there has been none.

clots. It is most noticeable in the early stages of the disease, as a rule. It is rarely profuse, as it generally is with tumors of the bladder and in some cases of malignant disease of the kidney. It is not increased by exercise, as it is apt to be in cases of stone, nor by instrumental examination of the bladder, as it often is in cases of bladder tumors. I have never seen blood-globules absent from the urine on microscopic examination at any time. In one of my cases blood never appeared except microscopically. Exceptionally there are profuse hemorrhages; this I saw in one case. Tuffier has reported a case in which there were attacks closely resembling paroxysmal hemoglobinuria.

Pus in the urine is more rarely the first symptom, but it is often coincident with blood when the latter is first noticed. When it arises from the bladder, it is continuously present; when from the kidney, it is often variable in quantity; and if only one kidney be involved and its ureter becomes plugged, pus may disappear for a time, the freeing of the ureter being followed by its reappearance in the urine in large quantity. Occasionally small masses of caseous matter are seen in the urine; and it is to the lodgement of these or of a blood-clot in the ureter that its temporary plugging is due. As a rule, these plugs are dissolved or pressed onward into the bladder too soon to allow of the formation of a very marked pyonephrosis, but sometimes they are too large and firm to be so readily pushed down, and an extensive pyonephrosis is produced, advancing sometimes to the point of threatening rupture of the pelvis of the kidney. Such a threatening occurred in one of my cases on three separate occasions, producing the following phenomena: the sudden disappearance of pus from the urine, a diminution in the quantity of urine, pain in the left side, the appearance of a large tumor in the left loin, extending forward to the abdomen, and evidently connected with the kidney, and a marked rise of temperature. Twenty-four hours later there was a sudden reappearence of pus in great quantity in the urine, a disappearance of the tumor and of the pain in the side, and a dropping of the temperature. In the first flow of urine, following the reappearance of pus, there were numerous cheesy masses, of various shapes and sizes, one or two being quite large enough to have blocked the ureter. Occasionally such stoppage of the ureters will produce attacks of renal colic simulating those produced by renal calculus.

There are two points in connection with the pyuria of renal and bladder tuberculosis that I do not remember to have seen noted by writers on the subject, which I have observed in several of my cases, namely, that the pus has a peculiar dirty-gray color, and that these tuberculous urines even when loaded with pus, do not, in many cases, have the exceedingly foul smell that is often noticed in the urines of some cases of chronic cystitis in connection with prostatic hypertrophy, and more especially of malignant disease of the kidney and bladder.

Unlike blood the pus generally increases in quantity as the disease progresses, although in some instances it undergoes marked temporary diminution.

Painful and frequent urination are also early symptoms. Very often the first thing that attracts the patient's notice is a slight increase in frequency of, and a teasing desire for, urination; this may precede the appearance of pus or blood in the urine by several weeks or months, and be the only symptom. There is nothing especially characteristic with regard to the pain in the earlier stages; later, however, the occurrence of very marked remissions, when they take place, as they do in some cases without any apparent cause, is a very suggestive feature. These remissions of pain are usually associated with a diminution of pus in the urine. Unlike the pain in cases of stone, that of tuberculosis, when the bladder is involved, is worst when the bladder is full; and it is not so markedly increased by exercise as it is in stone.

Bladder irritability is often very marked when the disease is still confined to the kidney; and it is this, as I have said, which sometimes causes the mistakes in diagnosis, through considering the trouble to be an ordinary cystitis.

Before leaving the symptom of pain, let me say that as the disease advances it becomes almost intolerable; it is worse than that of stone because almost incessant. I think I have never seen greater suffering, except in cases of cancer of the bladder or prostate; and yet, even up to the last, there continue to be unexcepted periods of relief in some cases.

Two strikingly characteristic features of renal and bladder tuberculosis are (1) the extraordinary remissions in the severity of many or all the symptoms, and (2) the entire failure of the ordinary medicinal remedies to relieve the bladder symptoms, and the positive aggravation of the latter by local treatment, such as bladder washes, deep urethral injections, or the passage of instruments. The remissions are very deceptive, and often raise false hopes.

There is one other thing that I have observed in this series of cases, and that is, the comparatively rare occurrence of chills and profuse sweats that are so frequently seen in connection with cases of suppurative nephritis, of the so-called surgical kidney. In concluding these notes on some of the especially suggestive symptoms of this disease, let me repeat what I said at first, that the appearance in the manner described of bladder irritability, of blood in the urine, and of pus, is, in the absence of any of the special causes mentioned, particularly if occurring in a male under fifty years of age, highly suggestive of renal or bladder tuberculosis. To establish the diagnosis, there remain the discovery of the tubercle bacilli, and the cystoscopic examination of the bladder.

### SURGICAL TREATMENT.

Of this I shall only give a very brief outline. The outlook is not hopeful for surgical interference, but it can often avert immediate danger, and relieve pain sometimes. If I should judge from my own experience, I should say that local treatment of the bladder when it is the seat of the tuberculous process is for the most part unavailing. I have had no success with applications to the bladder, and have tried thoroughly emulsions of iodoform, solutions of nitrate of silver, boracic acid, permanganate of potash, and so on through the whole list. Dilatation of the female urethra sometimes gives short periods of relief, but often fails to do so. Deep urethral injections are, so far as I have seen, injurious. Long-continued drainage of the bladder through the perineum has failed to relieve, in my hands. In two cases in which suprapubic cystotomy was done for the relief of most distressing vesical tenesmus, the operations were partially successful, especially when supplemented by applications. Iodoform applications after curetting

the ulcerated surfaces of the mucous membrane of the bladder, afforded very considerable relief in both cases. Guyon has reported two cases of what he considered to be primary tuberculosis of the bladder, which he treated by suprapubic cystotomy, and by burning the ulcerated surfaces with the actual cautery; one of these he reports as cured, the bacilli having disappeared from the urine, and the patient being freed from all symptoms one year later. The second patient did well, but the bacilli did not disappear.

With regard to the prospect of success attending operations on the kidney, the statistics published by Newman and others are of interest. Facklam[3] reports as follows:

He collected 108 cases of tuberculosis of the kidney, in 20 of which nephrotomy and in the remainder nephrectomy was performed.

Two-thirds of the patients were women. The percentage of cases with reference to age is shown below:

| | |
|---|---|
| 1 to 10 years | 7 per cent. |
| 11 to 20 years | 9.4 " |
| 21 to 30 years | 37.6 " |
| 31 to 40 years | 37.6 " |
| 41 to 50 years | 7 " |
| Over 50 years | 1.2 " |

In 38 cases out of 72 the diagnosis was correctly made before operation.

The following conclusions are drawn from a study of the operations and their results:

The mortality attending the operations in the 20 nephrotomies was about 60 per cent.

Of the eight patients who recovered, four only are claimed as cures; and of these but one resulted in a well established cure.

Of the patients who died within a short time after the operation, five had had the disease for several years previously; two of them developed acute miliary tuberculosis immediately after the operation; one died of uremia (the other kidney was seriously involved by the disease); one died of acute septicemia; and in the remainder the disease was far advanced, or had involved other organs beside the kidney.

From this evidence the author concludes: "Thus far the results of nephrotomies in cases of renal tuberculosis are not favorable."

In 16 additional cases in which nephrotomy had been performed without improving the patient's condition, nephrectomy was done — resulting, in 10 of them, in very marked improvement.

Nephrectomy was performed in 88 cases, with a mortality of 28 per cent. In 13, the operation was performed through an abdominal incision, with four deaths (about 30 per cent. mortality). In 75, the operation was extraperitoneal, 21 deaths resulting (or about 28 per cent. mortality); but of these latter 16 can be said not to have died as a direct result of the operation, whereas the four deaths resulting from the abdominal operation were all due to shock, and followed immediately upon the operation.

Of the cases which recovered from the operation 62, or 70 per cent., are reported as wholly cured or greatly relieved, but of these only 14 had been under observation for over one year after the operation. Of these 14 cases, five are entirely cured, so far as can be seen; the rest are not wholly free from evidences of the disease.

As Vigneron[4] has pointed out, the success of nephrotomy in these cases depends on the thoroughness with which the pus cavities are opened into each other and cleansed, and freely drained. It should be remembered that hemorrhage is very profuse in resections or curetting of the kidney substance, but it is usually readily controlled by firm packing. A summary of the article of Vigneron above referred to, relative to these operations on the kidney in cases of tuberculosis is here submitted.

Dr. Vigneron points out that surgical interference in cases of renal tuberculosis dates back only twenty-five years, and that the subject has been exhaustively treated only since 1890. He refers to the articles of Tuffier, Facklam and Heydenreich as the most recent and important contributions to the subject; and he compares his own conclusions — arrived at independently — with those of the other surgeons just named, as follows:

NEPHROTOMY IN RENAL TUBERCULOSIS.

Facklam: 36 cases, general mortality 33.33%, operative mortality, 13.88%.

Vigneron: 54 cases, general mortality 38.18%, operative mortality, 12.72%.

Vigneron advises against early surgical interference in renal tuberculosis, following in this respect the teachings of Professor Guyon.

His conclusions in regard to nephrotomy are, that the operation affords relief in many cases, and that radical cure may follow its performance in some rare instances. In this connection, he cites the case of a child upon whom Guyon performed a nephrotomy six months before, and whose general and local conditions showed such remarkable improvement that a permanent cure is looked for.

He considers nephrotomy indicated when the patient is suffering, is losing ground, and when both kidneys are affected.

The success of the operation depends upon the manner of its performance. It is essential to open freely *all* pus cavities, and to remove, so far as possible, all cheesy masses; to drain freely; and to suture the edges of the renal wound to the lumbar incision, so as to allow the interior of the kidney to be easily cleansed and dressed. If these steps are not taken, the operation is useless.

The following figures are given in regard to nephrectomies:

(1) ABDOMINAL.

| | | | |
|---|---|---|---|
| Tuffier | 11 cases, | mortality, | 26.3% |
| Facklam | 13 " | " | 30.0% |
| Vigneron | 19 " | " | 26.84% |

(2) LUMBAR.

| | | | |
|---|---|---|---|
| Tuffier | 45 cases, | mortality, | 28.2% |
| Facklam | 75 " | " | 28% |
| Vigneron (primary) | 65 " | " | 40% |
| Vigneron (secondary) | 20 " | " | 35% |

Vigneron accounts for the higher rate of mortality in the series of cases which he has collected by the fact that it includes a larger number of cases operated on in the earlier days of nephrectomy, when the technique of the operation was less perfect.

The author urges secondary nephrectomy rather than primary, and considers that if it is so done the mortality is much less than with primary nephrectomy. The best time to choose is a few weeks after a nephrotomy, as soon as the general condition of the patient has improved.

Nephrectomy should be considered only in those cases in which the disease is unilateral. Vigneron considers that renal palpation and the endoscope will,

[3] Arch. für klin. Chir., 1893, B. 45, H. iv.

[4] Annales des Maladies des Organes Genito-Urinaires, September, 1894.

in most cases, make a decision in this respect perfectly possible.

Nephrectomy should not, of course, be undertaken unless there is satisfactory evidence that the other kidney is not involved, which is not always an easy matter to determine. It is impossible to lay down any general rule that shall be applicable to all cases, that is to say, it cannot be asserted that nephrectomy should always be done in preference to nephrotomy, or *vice versa*. The rational plan would seem to be to make an exploratory nephrotomy, and to act according to the conditions found; for example, if the disease should be confined to a well-defined area of the kidney, not too extensive, a resection of that portion of the organ may be the best thing to be done, as recommended and practised by Czerny, Kummel, Bryson, and others. The patient's strength and the usual considerations that govern the surgeon in deciding whether it is safe to proceed to a grave operation after an exploratory one, will determine his course. It is thought by many surgeons that it is much safer to do a secondary nephrectomy in all cases; and the records of that operation so performed seem to point to that conclusion.

## THE HISTOGENESIS OF THE PLASMODIUM MALARIÆ.[1]

BY F. A. ROGERS, M.D., CHATHAM, MASS.

The only break in the chain of evidence which would establish beyond a doubt the fact that malaria is caused by a specific micro-organism is the one criterion that the parasite has not as yet been successfully cultivated upon artificial media. But the observations of many trustworthy investigators conclusively prove that such is the case, although we cannot as yet successfully watch the wonderful changes which occur in the plasmodium when in its natural element, the blood, in the test-tube.

The parasites belong to the sporozoa, and have the definite name of plasmodia malariæ. They are always found in the blood of persons who are suffering from malaria and are not found in the blood in other conditions.

Malaria is perhaps the best example we have of a purely miasmatic affection, never appearing as an infectious disease, and cannot be communicated directly from one person to another except by inoculating a healthy individual with the blood of one sick with the disease. This fact, which has been successfully demonstrated by experimenters, proves that the infectious matter exists only in the blood.

The forms which have been discovered in this disease are peculiar to it alone, yet one point remains undecided, namely, whether there is only one kind of a micro-organism or whether several kinds give rise to the varying conditions known as tertian or quartan fever.

Laveran maintains that a single parasite causes malaria, and that the various forms met with have no connection with the various clinical phenomena found in this disease.

Golgi, on the other hand, is of the opinion that the diverse forms of malaria are caused by several different morphologically distinct species of plasmodium. He further maintains that upon the cycle of development of each parasite the various clinical manifestations of malaria depend.

Meade Bolton, in a short article upon plasmodia malariæ, has carefully compared the different views of these observers, and, according to him, Golgi regards the ameba or plasmodium of Marchiafava and Celli as the fundamental form of the organism. It is described as a more or less round mass of protoplasm, an irregularly formed structure, containing no pigment granules, and endowed with ameboid movement. He further maintains that the parasite occupies a position inside of the red blood-corpuscles, where it has been found by Councilman in sixteen cases, deriving its nutrition from the hemoglobin, and that it goes through many or all of its phases of development, even to reproduction, therein.

On the other hand, Laveran holds that the plasmodia are not found inside of the blood-corpuscles at all, that at most they are simply attached to them, whereas many forms are found floating around free in the blood plasma. He further maintains that the fully developed organism is represented by moving filaments which are developed within small cystic bodies; afterward becoming detached from these they move about freely in the blood.

To Laveran, in 1880, belongs the credit of first discovering the parasitic nature of malaria, but a different interpretation of the phenomena observed has given rise to the different views as outlined above.

The ease and certainty with which an examination can be made when one possesses a microscope is indeed novel. No elaborate apparatus or expense is entailed except a slip of glass, a thin cover-glass and a sterilized needle which complete the outfit. Different observers select different parts of the body from which to obtain a drop of blood for examination. Sometimes it may be the lobe of the ear, finger-tip, wrist, or even an organ like the spleen. With a view of obtaining blood as free from pain as possible I know of no method better than the following: after cleansing the left forefinger apply a handkerchief like a tourniquet tightly around the finger between the second and third joints, then directing the patient to strongly flex the finger it becomes so filled with blood that a very light prick with a sharp needle made at the junction of the palmar and dorsal surfaces of the finger will without pain give a plentiful supply of blood.

Two methods of procedure are now before us: the immediate, or examination of the fresh blood; and the mediate, or examination of a properly prepared, stained, and mounted cover-glass of blood. Both methods are very easily practised, and both should be tried in a given case. For the immediate examination, after wiping away the first drop of blood which appears, simply touch the centre of a clean cover-glass to the drop of blood and apply it to the glass slip, when it is ready for examination. If an appliance for warming the stage of the microscope be at hand the ameboid movements will be more apparent.

For the other method a different procedure, though one nearly as simple, is needed. It is necessary to have a thin, even layer of blood spread upon the cover-glass and properly fixed in this condition. Nothing in my hands has worked so well for a blood-spreader as a square cover-glass mounted in the handle. The split end of a match answers well for a handle. The free edge of this cover-glass is dipped in the blood and then drawn across the face of a clean cover-glass when,

[1] Read before the Barnstable District Medical Society, November 20, 1894.

if properly done, a thin, even layer of blood, scarcely more than the thickness of one corpuscle, will be left upon the cover-glass. This is now fixed by being placed in equal parts of absolute alcohol and sulphuric ether for twenty to thirty minutes, after which it is to be stained in an aqueous solution of methyl-blue or in Biondi's triple stain; then, after washing in water and drying, it is to be mounted in Canada balsam, when it is ready for observation. If no special or prolonged study of a case is needed, then the first method is to be commended, and especially if simply a diagnosis is all that is required. A satisfactory examination of the plasmodia can only be made by employing a high-power objective; a one-twelfth or one-fifteenth-inch objective will not be too ample to show the various forms well.

An excellent summary of the facts established in regard to the etiology of malaria is given by Marchiafava as follows:

(1) Malaria is a parasitic disease caused by a hematozoon belonging to the protozoa and not by a bacillus.

(2) The malarial hematozoa are amebæ which develop inside the red blood-corpuscles, changing the hemoglobin into melanin.

(3) The amebæ complete their cycle of life in the red blood-corpuscles. Beginning as unpigmented moving bodies they develop, becoming pigmented, and multiply by segmentation into spores which becoming amebæ enter again into the red blood-corpuscles, thus completing the cycle.

(4) This cycle corresponds to the periodicity of the attacks.

(5) During the course of their development a poison is produced which effects a change in the blood-corpuscles as well as the organs.

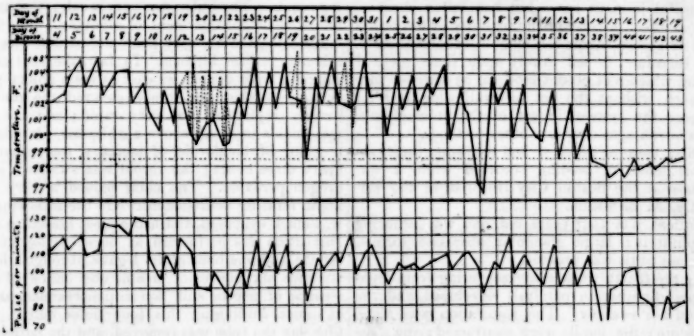
(6) Each type of fever has its own peculiar variety or species of ameboe — and these differences are apparent upon close observation.

Up to the present day these facts have become quite well established; yet, could we furnish a medium outside the body upon which the plasmodium would successfully grow and reproduce the cycles as observed in the body, and use the parasites for experiments of transmission, a clear insight into the pathology and epidemiology of malaria might be obtained.

On the protozoa theory intermittence is readily understood. The apyrexial period is equivalent to that of incubation; the onset of fever is the period of accumulation, while the subsidence of fever corresponds to the period of elimination of the poison. The amount of poison generated at one time is proportionate to the severity of the fever.

As all varieties of malarial disease may prevail at the same time and in the same place, as the sequelæ of all the manifestations are identical in character, and as likewise the acute manifestations of all varieties are amenable to the action of antiperiodic remedies, it might be inferred that there is but a single noxious germ which, under varying conditions, causes the various forms of malaria. Having demonstrated that the cause of malaria is a protozoon, the question naturally arises, whence its origin and how is it communicated to man. In the widest acceptation of its meaning malaria signifies bad air, or air which has been rendered so impure by noxious exhalations, or from any cause, as to produce injurious effects in the human system.

An analysis of the gaseous products of decaying vegetable matter reveals the fact that they consist chiefly of carbonic acid, carburetted, sulphuretted and phosphoretted hydrogen and ammonia. Experiments with each and all of these gases fail to produce the effects ascribed to malaria. Thus far eluding all methods of investigation, there appears to remain in the exhalations from certain soils a subtile, poisonous agency which cannot be isolated and experimented with, but which is only found after it has entered the blood.



The agents necessary to produce these emanations are said to be heat, moisture and dead vegetation. Heat alone is not sufficient to induce malaria, as in some countries where the heat is extreme there is freedom from this disease. Neither is the sudden transition from heat to cold sufficient to cause it, as instanced in the sandy deserts where cold nights succeed hot days. Moisture alone or associated with certain temperatures, will not induce this malady, for we find in fogs occurring at sea a harmless condition. But dead vegetable matter, in connection with a certain degree of heat and that proportion of moisture favorable to the processes of decomposition, is regarded as essential to the evolution of this parasite. The presence of low grounds, marshes and swamps in temperate climates afford that conjunction of agents most favorable to the evolution of this poison.

This miasm is assumed to arise during the retrogression of organic matter to the inorganic state under the favorable conditions of heat and moisture. But there must be a certain relation of these factors, one to the other, as in case of excessive moisture when the ground is wholly covered with water there is no malaria; it is not during the period of the overflow, but during the subsequent period of drying up of the water, with the needful conditions added, that this disease prevails.

Again, it is not necessary for an inundation of a previously dry soil to produce this result, but the artificial draining of ponds or the accidental breaking of dams has been followed by an outbreak of this malady in their vicinity. The vicinity of a miasmatic marsh may not be an insalubrious locality for habitation, for where a steady wind prevails during the sickly season people living to the windward side may not be affected. The direction of the wind, especially if it be across a malarial area, may affect persons living in the adjacent upland country several miles distant. If one of the factors which cause malaria be removed, an improvement in the general condition ensues, as in drainage, which from remote ages has been regarded as the best method of improving malarial soil. In order that malaria should be generated, it is necessary to have a certain degree of humidity, a soil containing decaying organic matter, and a temperature of over 60° F.; yet when these conditions exist, malaria does not always abound. How then shall we account for the apparent exception to this rule? One other factor is supposed to wonderfully influence the evolution of this parasite, and that is the effect of growing vegetation. Dr. H. C. Wood, in his chapter on miasmata, mentions the fact that living vegetation destroys malaria during the process of its growth. When the proper relation exists between the miasm generated and the capability of the growing plants to dispose of it, no malaria prevails, although the factors necessary for its generation are in abundance. Either through the roots or leaves, or probably both, the whole or a greater part of the malaria generated may be assimilated, and thus there will be no evolution of the

miasm. It is only when this relationship between the malaria on the one hand, and the assimilative power of the verdure on the other is disturbed that the malarial poison affects the human organism. Several observers have in times past announced the discovery of this protozoon outside the body, but in no instance could it be proven.

Malaria is frequently combined with another poison in the human economy. One frequent combination is with typhoid fever. It has been thought that these two diseases were antagonistic; but the truth seems to be that they may be and are often combined in the same individual at the same time. How then shall it be determined? Those who have had large experiences in typhoid fever are prepared for wide clinical variations, so that not alone upon the clinical manifestations can we rightly judge. No other way is left but a microscopical examination of the blood.

The term "typho-malarial" fever does not designate a new or distinct type of disease, but is a term which is conveniently applied to the combination of malaria and typhoid fever in the system at the same time. We should at least expect that there would be as large a mortality from the combination as from either alone; but such is stated not to be the case, for, according to a certain author, there were in a certain district forty deaths to every one hundred cases of typhoid fever alone, yet from the combination, typho-malarial fever, there was a mortality of only seven per cent. in the same locality. On the other hand, there can be no doubt but that numerous cases of so-called typho-malarial fever are simply mild cases of typhoid fever, so that considerable allowance must be made for the reports.

During the past season I have had quite an interesting case of the combination which we have just been discussing, and herewith present the clinical chart for inspection. It is not often that the physicians upon Cape Cod have the privilege of witnessing these cases, and this one did not originate there.

The patient, a boy of thirteen years, came from some part of Pennsylvania about one week before he was taken sick. Up to the day before I was called he had shown no unusual symptoms, in fact had been in bathing the second day previous. This case was fortunate in having a trained nurse, who carefully took the temperature and pulse at the prescribed time. According to the symptoms and clinical chart, the disease pursued a typical course for typhoid fever up to July 19, 1894, or the twelfth day of the disease, when the patient complained of "feeling cold" and of cold chills running down the back. At this time and subsequently there were marked fluctuations of the temperature during short intervals, followed by profuse sweating.

In the chart the continuous line marks the regular morning and evening temperature, and the broken or dotted line indicates the fluctuations observed between the regular times of taking the temperature. As will be observed, in many instances there were several degrees variation in a very few hours.

In the last week of typhoid fever we may expect marked variations of temperature, but occurring as it did in this case during the second week or median stage of the disease and without any clinical symptoms which would account for it, I was in doubt as to the cause until I had made a microscopical examination of the blood. There were found plenty of the plasmodia malariæ, which accounted for the symptoms and led to the employment of antiperiodic doses of quinine, which was followed by an amelioration of the symptoms. A chance was also given to study the effects of medicine upon the plasmodia. The spores, mature forms, and old cast-off shells, so to speak, of the blood cells, afforded interesting and profitable study for a long time. This, together with the fact that a positive diagnosis had been made, and also that the patient completely recovered after a trying and extended sickness, all produced in my mind a pleasant and valuable experience.

## THE VALUE OF THE STOMACH-TUBE IN FEEDING AFTER INTUBATION, BASED UPON TWENTY-EIGHT CASES; ALSO ITS USE IN POST-DIPHTHERITIC PARALYSIS.[1]

BY WILLIAM ALEXANDER MORRISON, M.D., EAST BOSTON.

One of the most serious difficulties met with by the physician who is called upon to treat the diseases affecting the throat is the inability of the patient to take a proper amount of nourishment. The cause of this is to be found partly in the mechanical obstruction produced by the swelling of the parts in certain diseases, or by paralysis of certain muscles in others,

[1] Read before the Suffolk District Medical Society, April 28, 1894.

and in part also by the fear of the pain or discomfort produced by the attempt to swallow.

This is especially true of cases after the operation of intubation of the larynx, where, owing to a mechanical interference with the act of swallowing, regurgitation of the food into the larynx may occur, causing a violent paroxysm of coughing. This is frequently quite sufficient to cause a child to absolutely refuse all forms of nourishment. As it is in diphtheria that we find these conditions present more than in any other disease, the importance of the subject becomes at once apparent.

We have in this disease an active and deadly infection which rapidly destroys the vitality of the patient, and a lack of nourishment at a critical time may baffle our attempts to aid the system to resist this poisoning, and may result in the gravest disaster.

Many attempts have been made to nourish patients under these circumstances. Rectal alimentation has proved useful in many cases, but has fallen short of the desired effect because of the inability of the bowel to retain or absorb the proper amount of nourishment. We are, therefore, forced to rely upon some method of feeding which will permit food to be carried into the stomach without the act of swallowing, and for this purpose the systematic use of the stomach-tube possesses advantages over any other method.

The first case in which I had the opportunity of using this mode of feeding occurred while I was house-officer at the Boston City Hospital, in the service of Dr. A. L. Mason.

The patient was four years old, and was suffering from diphtheria; large glandular abscesses formed and purulent otitis was present.

During the fourth week after recovering from diphtheria, post-diphtheritic paralysis developed, and the child could not swallow. The respiration was eight to the minute; the pupils were contracted; the face was pale; the condition torpid. Rectal enemata proving ineffectual, I resorted to the stomach-tube, at first using only a gag, and passing the tube through the mouth into the esophagus, but afterward found it more easily accomplished by lubricating the tube and passing it through the nose.

By this method I fed the child with the tube for four weeks, giving six ounces of cream, two ounces of brandy, three drops, three times a day, of tincture of nux vomica, and a digestive ferment. The patient was unable to cry aloud or speak during this time, but gradually made a complete recovery. Without this treatment, the child would undoubtedly have died.

The result in this case was so satisfactory and the method of application so relatively easy that I have continued this treatment for the past four years in my private practice. In cases of intubation it has proved especially satisfactory. During this time I have performed the operation twenty-eight times. Twelve children have recovered, or forty-three per cent. I have personally attended to every detail without the assistance of a trained nurse in any case.

To obtain satisfactory results, and to prevent undue exhaustion in the child, certain precautions must be observed. Two assistants are required. The child is rolled in a blanket with the hands by the sides. The first assistant sits in a chair near the bedside, and holds the child firmly in a reclining position upon his left knee. The second assistant holds the patient's head immovable. A soft-rubber catheter, to which a funnel is attached, is lubricated and introduced into the nostril with the eyelet on the under side, as it offers less resistance in entering the naso-pharynx.

For nourishment, cream with about twenty per cent. of fat is used; and to aid digestion, Metcalf's liquor pancreaticus and Fairchild's essence of pepsin in equal parts are used, also brandy, tincture of nux vomica, and tincture of digitalis. Any preparation of iron or any other liquid medicine may be added according to circumstances.

If bichloride of mercury or calomel has been employed, it is omitted after intubation, owing to its tendency to irritate the stomach and intestines. On several occasions iron or digitalis has caused some nausea after being administered through the tube, but on omitting them, this symptom has disappeared.

The following case proved very interesting on account of the emaciated condition of the patient, a child of six years who had just recovered from whooping-cough. The pulse was very weak; the urine contained one-eighth per cent. of albumen. The hygienic surroundings were very poor, the patient sleeping on a lounge in the kitchen. In fact, the poor child was suffering from neglect as well as from abject poverty. A grayish-white membrane covered the tonsils and uvula; respiration was very rapid; and the patient was unable to speak above a whisper. One-sixtieth of a grain of bichloride of mercury was administered every three hours; the throat was swabbed with hydrogen peroxide. The child passed a very restless night, refusing nourishment. On the following day it was much cyanosed, and had almost ceased to breathe. Intubation was performed at once, giving immediate relief; and one hour after, I gave through the stomach-tube six ounces of cream, one ounce of brandy, essence of pepsin and liquor pancreaticus, each half an ounce, continuing this four times daily. On the fifth day the tube was removed, and the patient made a good recovery, although in this particular case, she was unable to speak aloud for six weeks.

Another illustrative case was as follows: A child six years old had been ill for forty-eight hours without medical attendance. I found her breathing badly, and it was very evident that mechanical interference was needed. Half an hour after, intubation was performed with instant relief.

Having ascertained that during the last twenty-four hours the patient had only taken one teaspoonful of brandy with water and four teaspoonfuls of milk, I introduced the stomach-tube and gave at each feeding eight ounces of cream, two ounces of brandy, liquor pancreaticus and essence of pepsin, each two drachms; the pulse being rapid, five drops of tincture of digitalis was given.

Eight hours after, in coughing, the child expelled the tube. The breathing then appeared natural for a time, but in about ten hours I found it necessary to intube again, replacing the expelled tube with a larger one.

On the following day the patient coughed up a large amount of mucus having a disagreeable odor, and soon after most of the cream that was taken in the previous feeding was vomited. At the next regular hour for feeding, only four ounces of cream was given and liquor pancreaticus and essence of pepsin, each one-half an ounce, which were retained. From that time the patient took the full amount of nourishment, and at the expiration of five days was perfectly well.

To show the advantages of the stomach-tube in cases where intubation is not performed, the following case is interesting: A child four and a half years old was taken ill May 17, 1891. The tonsils and uvula were covered with membrane, the former unusually swollen, and in a few days a fetid odor was discernable. Ten days after formation of membrane, post-diphtheritic paralysis ensued, and the patient could not swallow. The pulse was very weak, the child could not rest day or night, crying incessantly. The mother became discouraged and said, when I mentioned stomach-tube, that she did not wish to torture the child, as she considered it a hopeless case. After much persuasion I resorted to feeding with the tube, through which was given on an average daily thirty ounces of cream, six ounces of brandy, essence of pepsin and liquor pancreaticus, two ounces each, twenty drops of tincture of nux vomica, and twenty drops of tincture of digitalis.

During the following week, the glands of the neck became very much swollen and discharged a great amount of pus; paralysis of hands and feet followed.

Treatment with the tube continued for about ten weeks, four times daily, when the patient was able to take some liquid food without regurgitation. At the expiration of four months, the child could walk quite well, but it was fully six months before he had entirely recovered.

Now these few cases illustrate fairly well the results obtained in all cases that have come under my observation during the past four years. In all my cases of intubation, this method and no other has been used. No nourishment has been permitted by the mouth in any case.

There has been no difficulty in most cases in the digestion of the amount of food given, and, after the first few times, the child has suffered little or no discomfort during the passage of the tube. In comparison with the ordinary method of feeding these cases, it possesses the advantage of permitting a definite amount of food to be given to the child at regular intervals, thus giving the stomach its natural periods of rest. It is quite true that the Casselberry postural method permits food to be swallowed fairly well, but the great difficulty lies in the impossibility of making the parents or nurses

| No. | Date. | Age. | Causes of Death. | Tube Worn. | Termination. | Remarks. |
|---|---|---|---|---|---|---|
| 1 | November 16, 1889 | 4 years | Septicemia | 48 hours | Fatal | |

| 26 | November 19, 1893 | 16 months | Heart failure | 12 hours | Fatal | |
| 27 | January 23, 1894 | 5 years | .... | 5 days | Recovery | |
| 28 | February 25, 1894 | 5½ years | .... | 5 days | Recovery | |

| | | |
|---|---|---|
| Between 1 and 2 years | 4 | Secondary tracheotomy performed in five cases; all died. |
| Between 2 and 3 years | 6 | Septicemia, two cases, both died. |
| Between 3 and 4 years | 7 | Extension of membrane, eight. |
| Between 4 and 5 years | 4 | Broncho-pneumonia, one. Pneumonia, one. |
| Between 5 and 6 years | 6 | Tube plugged, one; tracheotomy performed. |
| Between 6 and 7 years | 1 | Exhaustion, one. |
| | | Heart failure, two. |

realize the importance of this, and the child is permitted to take its food sitting up, with the result already stated. If a nourishment chart is accurately kept in these cases, the small amount actually taken is often appalling.

While this method of feeding is best carried out by the physician, it may, nevertheless, be taught to any intelligent nurse or parent.

In conclusion, we have, in feeding by the stomach-tube after intubation and in all other cases where there is interference with the act of deglutition, a method which is easy of application; which permits a definite amount of food to be placed in the stomach, thus fortifying the system against combined exhaustion and septic infection; which obviates both the discomfort and pain produced by the futile attempts to swallow; and which will also prevent the danger of deglutition, pneumonia or suffocation. Now, if extended experience shall show that it possesses these merits, it seems probable that we shall find an increase in the percentage of children saved from this most insidious and deadly disease, and much of the incessant care and trouble in their management prevented.

## THE DANGERS IN REMOVING FOREIGN BODIES FROM THE CORNEA.[1]

BY N. DARRELL HARVEY, M.D., PROVIDENCE, R. I.

THE subject of foreign bodies in the cornea is one which to most of us is so familiar and the treatment in the majority of instances so simple, that it may seem too insignificant a matter to bring to the attention of this Society this evening. But as there are not a few here who are called upon at times to treat this class of injuries, and as there are grave and serious dangers attending their removal in the ordinary way, a few words in that relation by me may not be out of place.

In a community like this, interested as it is in extensive manufacturing pursuits of various kinds, injuries to the eye from flying particles of metal and dust form a very large percentage of accidents; so much so is this the case, that in most of the large factories and mills, especially where the emery-wheel is used, some one man is to be found who from long experience has been looked upon by the other employés as possessing special skill in the removal of the foreign particles from the eye, no matter what their location. To such a man every injury of this kind is usually brought and an attempt at removal is made, which is often successful and leaves no permanent damage, especially if the particle be upon the lid or in the conjunctiva. But, as is more frequently the case, the foreign body is embedded in the cornea. This "skilled" mechanic, ignorant of the anatomical structure of the part and knowing still less of the first principles of cleanliness in such a case, to say nothing of antisepsis, with dirty hands, often pulls from his pocket his jack-knife (generally in use for cutting tobacco), and proceeds to attack the eye. Herein lies one of the most serious dangers to such a procedure. The foreign body itself is usually not aseptic, while the instrument which is often made to penetrate quite deeply into the corneal tissue reeks with filth. The dangers of suppurative infiltration of the cornea are thus certainly very great, and many eyes are lost by such infection.

I have seen several cases treated in this way in which the entire cornea was the seat of a suppurative inflammation starting from a pin-point wound caused by the impaction of a small piece of steel and subsequent botching attempts at removal.

Another cause of permanent damage to the sight is the resulting scar which follows such a wound, no matter how small. For the destruction of every particle of corneal tissue there is a resulting formation of connective tissue which remains as an opacity and affects the vision according to the size and density as well as its proximity to the centre of the cornea. So that we see the greater the area of cornea which has been injured the more extensive the scar, and the deeper the penetration of any instrument, the greater the resulting density.

Now the plan usually followed in these factories where such accidents are frequent is to locate the foreign body, and then without the use of cocaine (although in some places I believe this is now used) to jab at the particle or what looks like it, the patient endeavoring often at the same time to close the eye and dodge the impact of the knife, so that the instrument often falls short of its aim, impinging on and wounding a more remote portion of the cornea and laying it open to a resultant scar. I have seen many corneæ which have been the seat of several injuries of this nature so speckled with opacities from unsurgical procedures as to have the vision very markedly interfered with. I remember seeing a patient, who had gotten a small piece of steel in his eye and which had come out, with a hole in the cornea which almost involved its entire thickness. He had been operated upon by a fellow-workman, who had mistaken a pigment spot on the iris for a small foreign body in the cornea, and had punched away at the cornea until he had almost entered the anterior chamber. These are only a few of the many cases which all who have had to deal with such injuries see from time to time. Only a few days ago I saw the case of a man, an employé of one of the largest mills in this city, who had lost his left eye, and had gotten a piece of dirt into the right cornea directly over the pupil. A fellow-workman had worked at it, and scratched the cornea so that pain and inflammation arising, the man had become alarmed and been forced to seek medical advice.

I found the eye inflamed, and several scratches on the cornea near the site of the foreign body. A few drops of cocaine instilled into the eye soon relieved the sensibility, and a slight brush with a wisp of absorbent cotton immediately dislodged the foreign body. Had a camel's-hair brush or something of that sort been used in the first instance, it would have been enough to have removed the dirt and saved the patient the subsequent pain, to say nothing of the scars which will result from the needless knife scratchings of the cornea, and diminish the already poor vision in the only eye the patient had.

In view of the above dangers, I think the Society will agree that no cutting procedure, especially in unskilful hands, should be performed unless other means at removal have failed.

As quite a large proportion, if not a majority, of the foreign bodies in the cornea project beyond its surface and are not very firmly embedded, they can be easily brushed away. A very simple means which I have

[1] Read before the Providence Medical Association, December 3, 1894.

used for some years, and which I have no doubt many others have also made use of, is to take a wisp of sterilized absorbent cotton, and roll it on the end of a tooth-pick or cotton carrier, and simply wipe the cocainized cornea in the region of the injury. In a very large number of cases this simple means will dislodge the particle by its becoming caught in the loose fibres of cotton; and that is all, in a large number of such cases, that is necessary. The area around its point of impaction is not attacked, the least possible amount of injury has been done, and the resulting scar is reduced to the minimum. A plan used by Dr. Gould, of Philadelphia, and one which offers special antiseptic precautions is to dip the cotton in some antiseptic solution, as a solution of bichloride of mercury (1 to 5,000) or a solution of boracic acid (three per cent.) before applying it to the cornea, in this way also cleansing the wound caused by the foreign matters. This is all I claim that non-professional hands should attempt, for a large proportion of these injuries can be relieved in this way, and those cases in which further aid is needed, such as a cutting or a magnet operation, should be referred to a medical man who has the proper means and skill for such procedures.

Now, how shall we overcome this evil? As there are not a few members of this Society who have professional connections with many of the largest manufacturing establishments in this city, a great deal can be done by you gentlemen in pointing out to those in authority the dangers of using any instrument on the eye, and in suggesting the above much simpler and less dangerous method.

It would be a very easy matter for each establishment to provide itself with a bundle of tooth-picks, a small package of absorbent cotton and a little vial of a solution of bichloride of mercury (1 to 5,000). Then when an accident takes place, a perfectly safe attempt on the part of the employé can be made at removal; and in case of his failure to dislodge the offending particle, the patient can be sent to some skilled physician, and thus suffer as little permanent damage to his sight as is possible.

I trust I have been able to impress upon the Society the importance of avoiding these dangers in the treatment of this class of ocular injuries, and hope that others here to-night will express their experience and opinions, and add to the stress which I have endeavored to lay upon their proper treatment.

## Clinical Department.

### NOTES OF A CASE OF TUBERCULAR DISEASE OF THE KIDNEY.[1]

BY GRACE WOLCOTT, M.D.

M. L., twenty-five years of age, was seen at my office January 31, 1893. The mother and father were healthy. One sister had died of phthisis, and two sisters had died in infancy from unknown causes.

The patient said she had suffered for five years with offensive urine, for which she had received medical treatment at different times.

Her general condition was good, and the heart and lungs were normal.

The urine at this time had a specific gravity of 1.010; was cloudy in appearance, which did not clear on boiling; acid in reaction; contained no albumin, but considerable pus, and had a very offensive odor. Microscopically it showed abundant crystals of calcium oxalate, innumerable pus cells, a few vaginal epithelial cells, with fatty renal epithelium. The total quantity was three pints. Upon examining the bladder with a sound, a sensation was conveyed as of stone; accordingly that diagnosis was made, and the patient advised to enter the hospital for operation.

On March 6, 1893, she entered the Vincent Memorial Hospital, and two days following she was etherized, Dr. A. T. Cabot being present in consultation with myself and Dr. Ingraham. Examination showed the passage of the sound about eight inches, and a gritty sensation was conveyed by it. Operation was decided upon, and accordingly I made the usual median incision through the anterior vaginal wall, and long enough to give ample room to thoroughly explore the interior of the bladder.

The exploration showed an unusually capacious bladder, with no stone nor incrustation. The mucous membrane was somewhat rough, and small quantities of bloody mucus were brought away. A drainage-tube was introduced through the wound, and the bladder washed out with a solution of boric acid, the tube being held in place by silkworm-gut sutures.

The irrigation was kept up twice daily; but the urine continued offensive, and contained much blood and mucus, the blood, however, ceasing seven days after operation.

Five days after operation the wound had closed to the size of the tube; and on the twelfth day the tube was removed, and digital stretching of the fistula was begun.

On April 5th, just four weeks after operation, the temperature, which had been normal, rose to 103°, pulse 110; and she had chills, nausea, pains all over, and the conjunctivæ were much injected. The following day the pulse was 120 and weak, the temperature still 103°. She was cyanotic in appearance, had epistaxis, much pain in precordia, and her mind wandered. Examination of the heart showed a systolic murmur, with accentuation of the pulmonic second sound.

The question which presented itself to our minds was, Had we not a case of septic endocarditis to deal with?

She was closely watched, and fortunately soon began to improve. The urine still remained purulent; and on examination made April 18th showed the presence of tubercle bacilli. On the 26th, as the patient was opposed to allowing the fistula to remain longer, and as the urine contained no sediment, although it was alkaline and had a specific gravity of 1.010, the edges of the fistula were bevelled and sewed up with silkworm-gut and wire, union being perfect when the sutures were removed.

She was seen April 1, 1894, and reports that the urine, although still somewhat offensive, is not as bad as before the operation, but that her general condition is not very good.

I report this case as of interest after hearing Dr. Watson's paper. Our notice was called to the disease by a case which was under the care of Dr. Ingraham and myself in which Dr. Watson was called in consultation and which he has mentioned to-night.

In both cases the symptoms were those of bladder

[1] Read before the Suffolk District Medical Society, April 28, 1894.

disease; but in both we suspected the primary disease to be in the kidney, and in one of them the suspicions were confirmed. The case in which Dr. Watson was called in consultation was not verified by the actual finding of the tubercle bacilli, but in the other it was.

## Medical Progress.

### RECENT PROGRESS IN ORTHOPEDIC SURGERY.

BY E. H. BRADFORD, M.D., AND E. G. BRACKETT, M.D.

#### SCOLIOTIC SCIATICA.[1]

A NUMBER of articles which have been collected on the subject of this unusual affection would show that the symptoms are very varied in the different cases, so that it is almost impossible to classify them. There is usually a scoliosis with the convexity towards the lame side, the scoliosis being chiefly in the lumbar region and the upper portion of the spinal column has a less compensatory curve. The whole trunk is turned towards the sound side, and the lower ridge of the ribs press upon the pelvis. The upper portion of the body is inclined forward. The leg on the affected side touches the ground but the patient is not inclined to throw the whole weight upon it. The attitude is quite characteristic. Treatment of the affection is not always satisfactory. The scoliosis disappears usually after the sciatica has passed away. The galvanic current appears to be of value in these cases, as well as massage of the muscles of the affected limb. Stretching of the sciatic by forced manipulation and appropriate gymnastic exercises are of benefit. Kocher, in more severe cases, cut down upon the nerve and stretched it with apparent benefit, although the case is reported only a month after the operation.

Sachs[2] reports a case of what is called crossed form of scoliotic sciatica with a convexity towards the affected side, and which is due to an extension of neuralgia from the sacral to the lumbar plexus. Scoliosis develops itself gradually, first in the painful stage and second in the subacute stage. Pain is due to the pressure of the muscles in activity upon the irritated nerves. Besides the treatment of the sciatica the scoliosis should be treated by suspension and correction. Ranzier[3] reports a case of the sort where scoliosis remained after the cure of the neuralgia, and only gradually disappeared. Francon reports six cases treated at Aix les Bains.[4]

#### MALPOSITION OF THE VERTEBRAL COLUMN OCCASIONED BY THE PRESENCE OF A TUMOR, AND CURED BY EXCISION.

Dr. Gerard Marchant[5] reports two cases of fibrolipoma, situated near the spine in the lumbar region, which caused a lateral deviation of the spine, and was attended with marked subjective symptoms during locomotion. The first occurred in a large man, twenty-three years of age, appearing some time after a strain, which was supposed to be the starting-point of the tumor. The tumor was the size of one's fist, situated in the left lumbar region, and easily felt, the skin being movable over it, but attached below. Locomotion was extremely painful, the pain extending down the leg; but during recumbency there were no subjective symptoms. At the time of removal the tumor was found to be adherent to the muscle, which was also found to be atrophied to a marked degree. The recovery in this case was uneventful, the symptoms entirely disappeared, and health was restored.

The second case was that of a man of fifty-three years of age. The tumor was situated in the left lumbar region, with symptoms much the same as in the former. The tumor was removed, and at the time found to be adherent to the aponeurosis of the vertebræ. The recovery was uneventful, and the symptoms entirely subsided. Both tumors were found to be fibrolipoma. In the second were found several nerve filaments, which probably explained in a measure the severity of the symptoms.

#### CASE OF PRIMARY TUBERCULOSIS OF THE LAMINÆ AND SPINOUS PROCESSES OF THE VERTEBRÆ.

Dr. John C. Roberts[6] reports a case of disease which by autopsy was proved to be a case of primary tubercular disease of the laminæ. The case presented prominent symptoms of pain in the sides and abdomen during the earlier stages, with early paralysis of the legs and sphincters, and early development of bedsores. The deformity was slight, and differed from the ordinary kyphosis in that the swelling was on either side of the median line, and there was a depression over the spinous processes. An operation was performed to relieve the paraplegia, which was supposed to be due to pus in the canal; but the child died soon after, and in the autopsy it was found that the disease was a tubercular process which had attacked and destroyed the laminæ and had involved the base of the spinous processes.

#### A CASE OF ANCHYLOSIS OF THE SPINE.

Mr. William E. Miles[7] reports a case of anchylosis of the entire spinal column, the origin of which is not explained. The boy, at the age of twelve, was treated for cervical caries, with plaster-jacket and head-support for eighteen months, after which the spine is said to have been in the same condition of anchylosis as at the time of reporting, when the patient was twenty-one years of age. After the removal of the jacket he was able to do hard labor without ill effect, and the spine remained in the same condition. The three causes of tubercular, syphilitic and rheumatic origin are considered, but still leave the case as one of undetermined origin. Although the first symptoms of the disease may have been tubercular, there was nothing to suggest this in the way of spinal projection, abscess, etc.; nor would local disease in the cervical region explain the general anchylosis of the spine. Syphilitic origin has no support, either by history or other indications of the disease, and the same is true of the rheumatic taint. There later developed an enlargement of the ankle, which with the anchylosis is rather evidence of a general cause which manifested itself in these two locations. The case is worthy of mention from the rarity of the condition at the early age of twenty-one.

THE CAUSES OF PARAPLEGIA IN POTT'S DISEASE.

Dr. Ménard[8] has carefully considered this condition of paraplegia in Pott's disease, and a number of cases are given in which laminectomy was done; and although the author has presented little that is new, his review is of value in its corroboration of already well-accepted theories. In regard to the etiology of this affection, he accepts the usual belief that it is not due to the narrowing of the canal, but to the action which the tubercular focus itself exercises on the meninges and cord. He finds it rare in the cervical region, very rare in the lumbar, and extremely frequent in the dorsal. When in the last situation the abscess does not meet any muscular sheath which it can follow, it remains near the osseous lesion, submitted to the varying pressure of the lungs at each respiratory act, and later penetrates into the spinal canal. He favors in selected cases the operative treatment, and considers that the direct opening of a tuberculous focus causing compression offers a rational and effectual means of overcoming the paraplegia.

HEMATOMA OF THE STERNO-MASTOID IN INFANTS.

Dr. Gaudier[9] reports two cases in infants of hematoma of the sterno mastoid, which appeared during the sudden severe muscular contraction during vaccination. There is nothing of importance as regards the method of its occurrence, except that in each case during the vaccination the child turned the head forcibly away from that side, and during this severe muscular contraction a rupture of some of the fibres occurred, causing the ordinary conditions which are found after this accident. The cases are almost, if not quite unique, in that it is so seldom seen occurring some interval after birth. The author considers the usual form, and the relation that this may have to the etiology of the congenital variety, of which much has been written of late. By some authors it is considered that this is an accident caused by the pressure of the blade of the forceps, while by others that it is due to a forcible contraction of the muscles during its passage. In 68 cases of breech presentation, this condition was found to have occurred in 18, but it is also found after normal presentation, and also when there have been no forceps used. He concludes that in addition to the ordinary hematoma of surgical origin, in the new-born, there is also an identical condition with this other etiology; that being a trauma following later in the period of the first few months of life, and which as in the two observations cited, was due to the sudden muscular effort on the part of the patient, resulting in the rupture of a portion of the sterno-mastoid muscle. The symptoms and the prognosis of the treatment is identical in the two classes, and a cure without deformity should be expected.

TREATMENT OF SPASMODIC TORTICOLLIS.

Noble Smith[10] reports the results in five cases, in which section or excision of a portion of the spinal nerve was done, and in all of which there occurred a marked improvement, which lasted over the time of observation. In one, there was inability to walk but a short time; after the operation the patient was able to walk for an hour and a half and rapidly. The pain in the neck disappeared, and the deformity of the cervical spine also did not return. There was also an equally acute sensation on either side of the neck, and the motions of the head in all directions were without pain. The second case was in a man of fifty-seven, where there had been associated a painful tic of the face. After excision of the spinal nerve, the spasm quickly disappeared. In another, which had lasted four years, the contraction disappeared, but the deformity of the cervical spine remained. In another, the spasm of the rotators of the neck had not disappeared and required a second operation. Smith considers this treatment in a favorable way, and regards it as a valuable means of treating this persistent condition.

TORTICOLLIS OF RHACHITIC ORIGIN.

Dr. Phocas[11] reports three cases of torticollis occurring in young infants from ten to eighteen months of age, in which the deformity was apparently due to rickets. The diagnosis was made on the absence of the history of congenital defect, the instances having all occurred in cases of normal labor, and the condition having developed after some months of life. In none of these was there either contraction of the sterno-mastoid, or of the deep muscles of the neck, nor was there any evidence of paralysis as described by Guyon, while on the other hand the cases all showed evidences of general rickets. The treatment is directed toward that of the general rickets.

As diagnostic points, he mentions that his cases all occurred in natural birth, with no sign of deformity until later life. The deformity of the head consists of a turning of the head toward the shoulder, in all of his cases being to the left, with the production of a deep fold in the side of the neck. The chin is slightly elevated and the face turned slightly toward the right. When an attempt is made to correct the position of the head, there is little resistance met by the sterno-mastoid, but when left to itself, the head returns to its malposition. Usually lateral deviation of the head follows its throwing forward, and this position persists long after the torticollis has been corrected. The pain is not severe; yet the infants frequently resist manipulation, cry easily and frequently show a grunting respiration. The anterior muscles are not found contracted and only occasionally the posterior. In all cases the other evidences of general rickets will be found. The duration of the condition is usually of several months; the lateral deviation of the head disappears before the forward inclination, which usually persists for a long time.

PSYCHICAL TORTICOLLIS.

Brissand[12] gave the name of psychical torticollis to a peculiar form of wry-neck which is not due to any organic change, but which is apparently of a psychical nature. It is characterized by the inability of the patient to control by the will the muscles of the neck, although it is easy for the patient to correct by means of the hands the faulty position by a slight pressure of the finger upon the nose or upon the head. It is termed by the writer a local paralysis of the will. It is often accompanied by other neuroses and psychoses, neurasthenia, epilepsy and so-called functional spasms. This prognosis is doubtful. The treatment should be psychical.

### SPASMODIC TORTICOLLIS.

Richardson and Walton[13] report several cases of this affection, cured or improved by the removal of a portion of the supplying nerves, that is, the spinal accessory on one side, and branches of the cervical plexus on the other.

### AN EXPLANATION OF THE GREAT FREQUENCY OF RICKETS AMONG NEAPOLITAN CHILDREN IN AMERICAN CITIES.

Dr. Irving M. Snow,[14] of Buffalo, has collected the statistics of rickets among the different nationalities of Buffalo, and has from these studied the causes which lead to the frequency among the Italians. In his investigation, he studied the prevalence of rachitic children among the Italians in relation to the proportion among the other nationalities. The attempt is made in his paper to show that the disease among the Italians is due to the effect of the cold, damp, northern climate "upon the offspring of a race that has lived for many hundred years in the warm, dry, sunny air of Naples and of Sicily. It is the physical deterioration of a southern race in a northern climate. I hope to be able to prove that the usual causes of rickets — city life, improper feeding, acute or chronic digestive disorders, bad air, crowding in dwellings, uncleanliness, infectious disease—which produces rachitis in a moderate percentage of the children of the northern races, act with far greater frequency and virulence upon the first generation of Neapolitans born in America."

The Italian children about Buffalo are all the children of Italians who have recently immigrated; and he has found that they all come from the region round about Naples where their life has been passed out of doors in a warm climate. Their hygienic surroundings are fully equal to that of the other races about Buffalo. They are not crowded, being only about one hundred to an acre, and their food is fully equal to that of the Irish-Americans and the other races found in the city of Buffalo. The paper concludes quite conclusively that rickets develops rapidly among the first generations of Neapolitans born in this country, but the observations are not carried far enough to prove the influence that these same conditions would have upon the later generations.

### STUDY OF CHILD GROWTH.

Dr. Bayard Holmes,[15] of St. Louis, has reviewed the rather extensive work of Dr. Porter, of that city, who has collected the data from 34,354 school children, thus securing nearly 1,000,000 facts. Much of the work corroborates the facts which have already been well accepted in regard to the growth and development of children, particularly the relation between the sexes. A few points, however, seem to be comparatively new and deserve particular mention, as some of his tables indicate that the relative growth of children of different nationalities shows a decided difference, and perhaps in a measure accounts for the different figures which are obtained by observers in different cities. He also finds that in the pre-pubertal period the girls of the upper classes are heavier than the daughters of the manual laborers. From the fact, however, that so many are taken from school at about this age, the further observations of this as to whether this relation continues to be preserved cannot be so well studied. He finds that the period of slow growth of the girls is from six to eleven, or two years earlier than boys, and that after this age the girls are larger than the boys for a certain period, which is shorter with the larger girls than with the smaller. Among those with whom there is a rapid growth, the period in which the girls are larger than the boys is a period of three years and four months; whereas in the smaller types this period is three years and ten months. There is also an interesting relation found between their physical development and their mental capacity; for instance, the larger children seem to have more mental capacity than the smaller. The observations of the ages and weight of different grades show that of children of the same age in different grades the heavier children will be found in the higher grades. He urges a strict supervision over these children and the adapting of the work not only to their mental but to their physical ability. He suggests also that it might be well to remove the girls from competition during their stage of pre-pubertal acceleration, or adapting their work to their growth at this time. He also suggests that all the children who come under the mean percentage should be under the supervision of their parents. Those below the twenty-five-per-cent. grade should be under the supervision of a properly experienced physician.

### INTERNAL DERANGEMENT OF KNEE.

Messner[16] describes the dislocation of the meniscus of the knee-joint, as explaining the hitherto misunderstood cases of so-called internal derangement of the knee. He has met seven of these cases, and it is caused in his opinion by the rotation of the body while the foot is placed firmly on the ground preventing the rotation of the leg. A swelling is noticed at the outer side of the patella. The meniscus becomes displaced and is caught between the femur and the tibia, and presents an external prominence the thickness of a pencil between the inner side of the patella and the internal lateral ligament. To reduce the dislocation the knee is taken between the hands, the thumb pressing upon the projection. The swelling disappears suddenly, and the pain at the same time. The movement of the knee becomes free again. Messner is inclined to think that the deformity in the forearm of children as described by Goyrand is due to subluxation of the triangular cartilage. He has seen three cases of the elbow.

S. J. Mixter[17] reports six cases. In several of these there appeared to be a tear of the meniscus following the dislocation.

Lardy[18] reports two cases of tear of the semilunar cartilage, with removal and cure.

### MANUAL CORRECTION IN KNOCK-KNEE.

Zuffi reports a number of cases corrected at the Milan institution. He prefers in certain instances manual correction to osteotomy, in that he regards the latter as more dangerous. Mechanical treatment requires time. Manual correction can be done at any time, needs no instrument, is without danger and is certain. The operation is not to be undertaken under three, because the rachitic process does not cease before that time, nor should it be done over eighteen, as there is then danger of rupturing the external

[18] Révue de Chirurgie, 1894, p. 493.

lateral ligament. If there is much curvature of the thigh or of the leg, osteotomy is to be preferred. The external lateral ligament was not torn in 800 cases; and the danger of this accident is therefore slight. The supra-condyloid fracture need not occur if care is used; and even if it does, it is less injurious than a subcutaneous osteotomy. In performing the operation the patient is placed upon a strong table, the affected leg being placed upon a raised block. The assistant steadies the patient and fixes the pelvis. The second assistant presses the greater trochanter and the external condyle, and gives an opportunity for a direct application of force. The operator places one hand upon the malleolus and the other upon the calf. Force should be applied slowly, and gradually increased. A cracking sound shows the separation of the epiphysis. A plaster-of-Paris bandage is applied.

CURVED RESECTION OF THE KNEE.

Helferich [19] prefers in right-angled anchylosis of the knee instead of the ordinary wedge-shaped excision, the removal of a small portion of bone of a curved shape. In this way less shortening of the limb results as the cartilage between the epiphysis and diaphysis can be in this way avoided. A convex portion of the bone is sawed off from the end of the femur, and a concave from the tibia, and the leg is straightened; the incision through the soft parts is similar to what is used in ordinary excision. In order to prevent the narrowing of the popliteal artery by too rapid stretching, the author advises that the limb should after operation at first not be put up in a straight position, the position being improved later.

*(To be continued.)*

## Reports of Societies.

### SUFFOLK DISTRICT MEDICAL SOCIETY.

JAMES J. MINOT, M.D., SECRETARY.

REGULAR Meeting, Saturday, April 28, 1894, DR. A. L. MASON in the chair.

DR. F. S. WATSON read a paper on

SOME OF THE CLINICAL FEATURES AND THE SURGICAL TREATMENT OF PRIMARY TUBERCULOSIS OF THE URINARY ORGANS.[1]

DR. ABNER POST: A few years ago Dr. Bryson, whom Dr. Watson has quoted, who was at that time carefully studying genito-urinary tuberculosis, said to me the reason why we saw so few cases of urinary tuberculosis in Boston was because our attention was not drawn to it, that certainly a section of the country where tuberculosis of the lungs and other portions of the body was so frequent as in New England must certainly present many cases of urinary tuberculosis. My attention was, of course, drawn to the subject from that date more carefully; and the more my eyes have been opened to see such disease the more frequent are the cases. I have tried to find some reason to explain why we have seen so few, why cases are so seldom diagnosticated as tuberculosis; and it seems to me there are several reasons which partially explain it. Of course, our attention has been drawn to it very definitely only of recent years; but I think we are still too ready to accept certain cases of cystitis as idiopathic in character. Idiopathic cystitis, it seems to me, must disappear in the same way that idiopathic peritonitis has practically disappeared. Another reason seems to me to be that we are too ready to accept that form of disease which appears in the genito-urinary tract as a manifestation in some shape of venereal disease. We are too apt to approach such cases with the idea that venereal patients are liars, and that if their story fails to agree with our own preconceived idea it is still another manifestation of their tendency to conceal the truth. I have no idea of upholding venereal patients as models of truth and veracity; but it is the wrong attitude for the practitioner to hold towards them. It is not the way to arrive at the correct diagnosis, and perhaps the trouble is still more aggravated by what I believe to be the fact, that tuberculosis is not so infrequently superimposed upon a ground already diseased as a result of gonorrhea. Another reason, I think, why we lose some of these cases or fail to appreciate their true nature is because many of them appear in the testicle primarily, or at least the first outward manifestation to which our attention is drawn is in the testis. These cases are very often complicated by hydrocele, and the practitioner, seeing the hydrocele, is satisfied with the diagnosis of hydrocele. How often do we find a hydrocele which is tapped or which is undergoing radical cure complicated with a diseased testis, so that it is occasionally said that hydrocele is often complicated or accompanied by disease of the testis. It seems to me that we look at matters through the wrong end; it is better to say that hydrocele is a complication or a symptom of disease of the testicle. I am not prepared to say that hydrocele never occurs alone, but in the very large proportion of cases it is symptomatic of disease of the testis itself; and I think it would be possible to recite case after case in which the diagnosis of hydrocele had already been made, in which the testis was found tubercular. I can recall a case sent to me for radical cure in which the hydrocele was very evident. I had already begun to examine testicles pretty carefully under such circumstances, and I said to the young man that his disease was not hydrocele alone, but disease of the testis behind it. After the fluid was drawn off it was easy to make out the epidydimis, which was characteristic of tubercle, and I questioned him further. I found he belonged to a phthisical family, that he spent the winter in Florida with a brother who was highly phthisical and whose death was expected. These certainly are some reasons why we have overlooked the disease. I think another reason is that we are taught to expect in cases of tuberculous disease in the meninges, disease in the digestive tract, but the genito-urinary tract is not held up to us as a region in which to look for tuberculous manifestations. Certainly, Dr. Watson has spoken so far only of tuberculosis in the urinary tract as a primary disease. It is sometimes extremely difficult to know whether the disease is primary; and its complication with tuberculosis in other places certainly deserve study for a special reason, because of the difficulties of treatment, which are just as difficult in secondary as in primary tuberculosis. The operative treatment is certainly sometimes beneficial, but there is one additional reason why it should not be too freely carried out, and that is the difficulty with

[1] See page 121 of the Journal.

[19] Langenbeck's Archiv., Bd. 46, H. 3.

which operative wounds are induced to heal. I had this winter a striking example of it in a comparatively young man who had tuberculosis of the bladder and probably of one kidney also. The pain which that young man suffered was intense. He had been examined for stone once or twice with no benefit, but rather with an increase of the symptoms. The pain was so great that he was constantly under the influence of morphia, and cocaine was also daily administered. With the hopes of benefiting him somewhat, I made an incision through the perineum hoping I might find some spot that could be curetted. No such spot appeared, but I was able to establish complete drainage of the bladder and by careful treatment afterwards, the instillation of iodoform oil being one of the important methods of treatment, I succeeded in giving the man very great relief, so that he was enabled to dispense entirely of morphia and cocaine. There was at least a temporary improvement in his general condition; but at the end of three months, which was the last time I saw him or heard from him, the wound in the perineum was still unhealed, and that is the third wound in the perineum which I have seen which has failed to heal after a reasonable length of time. One of them was a fistula in the first place, which followed a bruise in which tuberculosis was shown to exist in that patient by disease in both testes and by the discovery of the tubercle bacilli.

DR. THORNDIKE: I am very glad Dr. Watson has taken occasion to read a paper on this subject, because, as Dr. Post has said, our knowledge of the clinical history of urinary tuberculosis is very slight and it is only by the accumulation of such individual experiences that we can hope to enlarge it to any extent. It is true, I think, that urinary tuberculosis is not a rare disease, but exists in a good many cases and sometimes for a very long time without manifesting any symptoms approaching acuteness. When such symptoms do arise, symptoms which lead to the patient's seeking advice, the clinical knowledge at the disposal of the practising physician is so comparatively slight that faulty diagnoses are frequent, and the trouble is very often overlooked. Urinary tuberculosis is rarely localized in one organ. In whatever portion of the urinary tract it may have its origin it spreads, as a rule, with great rapidity, covers in a short space of time a sufficient area to give rise to symptoms of very varied kinds, so that the clinical picture may direct the attention of the physician to an organ at some distance from the real seat of the disease. For example, we very frequently have a tubercular pyelitis with exclusively bladder symptoms, symptoms which point to an uncomplicated cystitis; and these bladder symptoms may not be simply symptoms of reflex bladder irritability, but symptoms directly dependent upon coincident tubercular disease of the prostatic urethra and neck of the bladder. The diagnosis is not easy to make; and if the experience of careful observers can be formulated, much light will, of course, be thrown upon the clinical side of tuberculosis in the urinary tract, and many of the cases of so-called idiopathic cystitis will undoubtedly be explained. Dr. Watson has begun such a formulation in his paper. Without attempting to discuss the individual symptoms which Dr. Watson has detailed at some length, I will only say that in my belief all cases of chronic inflammatory disturbance of the urinary tract which have not yielded to careful treatment, which have been distinctly excited and made worse by any instrumental interference, or which have had unaccountable exacerbations, should be suspected. They should be carefully watched for any hint which may lead to a better clinical diagnosis. Of course, the only way to verify that diagnosis is by means of the microscope; but if we have a series of such papers as we have had to-night, I think we may have a distinctly better idea of the clinical nature of these diseases before very long.

DR. GRACE WOLCOTT: In regard to the case Dr. Watson mentioned, it was of a girl nineteen years old. She was seen in January, 1891, and then had very great trouble from incontinence, which brought her to desire some active interference. She was seen in April, 1891, by Dr. Watson, who performed the operation. She had the signs of recovery of which Dr. Watson spoke. She came into the hospital weighing eighty-five pounds, and gained rapidly in weight after she got over the immediate effects of the operation. She died eighteen months after operation.

Dr. Wolcott then presented

## NOTES OF A CASE OF TUBERCULAR DISEASE OF THE KIDNEY.[2]

DR. REYNOLDS: I am not fitted to speak of this subject as regards tuberculosis of the male bladder, and am unable to speak from my own experience of tuberculosis of the female bladder, but I am somewhat surprised that in the discussion no reference has been made to the work recently done by Dr. Kelley, of Baltimore, on this subject. Kelley has succeeded in demonstrating that tuberculosis of the female bladder is commonly accompanied by tuberculosis of the ureter, upsetting the former impression that such diseases almost invariably skip the ureter and localize themselves in the bladder or kidney. I had the pleasure last autumn of seeing Dr. Kelley demonstrate three cases of tuberculosis of the bladder which he had at that time under treatment, and of interviewing the patients myself to get their impression of the results of treatment. All three patients agreed most heartily with Dr. Kelley in the statement that their symptoms had been entirely relieved with great rapidity during treatment. The condition of the bladder of the patient who had been longest under treatment was much better than that of either of the others, and Kelley assured me she had been originally as badly off as either of the two others he showed me. He was treating them, so far as the bladder was concerned, simply by local applications every day or every other day, of a solution of nitrate of silver, under which the tubercular ulcerations seemed to be healing with considerable rapidity. So far as the ureters were concerned, his treatment was limited to the establishment of patency in the kidney by catheterization of it. I think that Kelley's work has not yet been carried on sufficiently long to enable him to make any statements about radical benefit. I think no one else has as yet an experience that dates back as far as his own. As far as the urinary organs of the female go, we are now able to deal with the disease very directly. I have been for some months now actively interested in Kelley's method of examination of the bladder, and can testify to the great ease with which the posterior and upper parts of the vesical wall can be brought under observation, and of the great ease with which topical treatment can be directed to them. I think it is perhaps an interesting question

[2] See page 131 of the Journal.

whether cystoscopy of the air-distended bladder may not prove of value in the male bladder. It is a question whether the treatment by topical applications of nitrate of silver is not to prove of value.

DR. WATSON: I am very glad that Dr. Post and Dr. Thorndike confirm the impression which I have, and which was the reason for my presenting this paper, namely, that this disease is not recognized so often as it should be in this neighborhood; and I think that if the symptoms which are the most characteristic are borne in mind it is much more likely to be noticed oftener. In regard to the treatment of Dr. Kelley, I have never treated cases by this method. I have treated cases by the application of nitrate of silver to the bladder in the ordinary way, and remember two in the male early in my series in which the increase of the local symptoms was so great that I desisted. I do not think I have ever seen such intense pain as was set up. The nitrate of silver treatment in the ordinary way has been tried by Guyon and his school with some success. I doubt whether it will prove a panacea.

DR. W. A. MORRISON read an account of

### THE VALUE OF THE STOMACH-TUBE IN FEEDING AFTER INTUBATION, BASED UPON TWENTY-EIGHT CASES.[2]

DR. WHITNEY: I think the importance of the subject Dr. Morrison has presented to-night is very great. Forced feeding or gavage, as it has been termed, has received very little attention until quite recently from men who are treating these cases. The principal investigator in this country has been Dr. Holt in New York, who has used this method of feeding, and in a discussion before the New York Academy of Medicine about a year ago reported certain of the results he had obtained by forced feeding through the stomach-tube. In an article published in to-day's *Medical Record* he reports still further results from this same method. He described the results obtained from some four hundred cases treated in three New York Infant Hospitals. His method has been very satisfactory indeed to himself, and has consisted in passing a tube through the mouth into the stomach instead of through the nose. The first case I think was treated by the nasal tube. I think that the advantage of the nasal administration of food through the tube is a very distinct one indeed. The method by the mouth means using a gag, the possibility of its slipping, and the possibility of the child biting the tube. My experience in using the gag in intubation has convinced me that it would be more satisfactory to have a straight passage through the nose into the stomach when using the feeding-tube. I think, in cases of intubation, the results are especially satisfactory, and it is in this class of cases that I am particularly convinced of the value of this method. The great obstacle in the treatment of cases of intubation has been in the past that it was almost impossible to get the child to swallow, and many surgeons in the beginning gave it up on account of that difficulty and returned to tracheotomy. Several attempts were made to overcome this difficulty by mechanical means. Dr. Ingalls, of Chicago, invented a hinged-tube which failed absolutely. Others who followed him in modifications of the tube shared the same fate. The most satisfactory advance in the treatment of these cases took place when Casselberry pointed out that lowering the child's head was sufficient to obviate all difficulty. When that can be carried out it is all very well; but the position is so unnatural that a child always objects to it, and the problem resolves itself into forcing the *parents* rather than the child to submit to it. So far as I have seen, they object from a feeling of sympathy to disturbing the sick child, and it takes the nourishment as it pleases, and coughs and strangles. I do not think the refusal to take food after intubation always depends upon dysphagia, but sometimes upon anorexia; and it seems to me a great comfort if we can place in the child's stomach a definite amount of cream and peptonized milk and brandy and medicines, and feel it is going to be assimilated. After the relief of dyspnea by the tube, which is almost always complete, we have simply a case of diphtheria to treat; and the treatment of diphtheria seems to me to be resolved into the question of nourishment and stimulation, aside from the local treatment, and this cannot be done, I think, satisfactorily in all cases. I can recall cases which would have been saved had this method been used. Dr. Morrison's percentage of recoveries, I think, is something to be proud of. So far as I am familiar with series of the same number of cases I think it is the largest. In seventy-eight cases I reported before this Society a year ago the percentage of recovery was about thirty-three. Those I have done since then have made the total number about one hundred, and I have not been so fortunate in my percentage of recovery, so that I think it is about thirty, which is about the average; and I think that percentage of recovery may be increased a good deal by forcing the nourishment systematically. I think that this method can be taught easily to a nurse. I am sure we all appreciate the care and industry Dr. Morrison has shown in treating these cases. One point I should take exception to is his abandonment of corrosive sublimate. I am still of the opinion that of internal methods it is as good as any we have. Jacobi was, I think, the first to bring out the treatment, and is still a believer in it. I have seen cases in which the membrane disappeared from the fauces and reappeared after its discontinuance, and I have not seen much irritation of the stomach or bowels. I am sure that the amount of labor required in personally attending to all the details of these cases is well worthy of our appreciation; and I am quite sure we that shall be under obligations to him for leading the way to a proper treatment of this class of cases.

DR. PRESCOTT: It is so late I think there is little to be said about the treatment of diphtheria and the method of feeding by the stomach-tube, except to say that anything that will make it easier to feed a child, especially after intubation, is to be welcomed. The few cases that I have seen have not been as satisfactory as Dr. Morrison's have been, because of the difficulty in the cases in which it was tried of getting the tube through the nose and throat, owing to the filling up of the pharynx and the nose with false membrane; but it seems to me that in cases where the tube can be easily passed it must add a great deal to the chance of the child's recovery.

DR. MORRISON: I desire to remark that if one finds it difficult to pass a medium-sized soft-rubber catheter, a smaller one may be used.

---

DIPHTHERIA IN LONDON DURING 1894. — During the year 1894 there were 13,694 cases of diphtheria reported in London, with 3,195 deaths, as against 1,962 deaths in the previous year.

## THE ETIOLOGY OF CARCINOMA.

THE etiology of carcinoma remains one of the darkest subjects in pathology, in spite of the numerous theories which have been advanced to explain it. Of late the parasitic theory has been the most prominent. In the last five years many articles have appeared describing structures within the tumor-cells, which are supposed to be parasites belonging to the sporozoa. The most different structures in the cells, and in general any structures which assume the appearance of a foreign body in the protoplasm, whatever their morphology, have been considered as parasites. Many of the bodies described in the cells have some similarity to known forms of unicellular organisms, others not the least. Most authors have regarded these parasites as the direct cause of carcinoma. By others they have been regarded as only accidentally present. Not only these structures within the cells, but objects lying between the cells or at various places in the tissue, as the molluscum bodies in molluscum contagiosum, have been described as parasites.

Further interest has been given the matter by the discovery of parasitic unicellular organisms in the blood of man in malaria, and in the blood and tissues of birds and animals in a variety of conditions. There may be various explanations given of many of these structures in the tumor-cells which have been supposed to be parasites. Even when no explanation of their presence can be given, it is not rational to assume from this that they must be parasites. More or less isolated structures in the protoplasm of cells may be explained in a number of ways. Leucocytes may enter into the cell, degenerate, and finally lie as foreign bodies in a cavity within the protoplasm. One tumor-cell may become enclosed in the body of another in the process of growth, or one cell may lie in a depression in another cell and then appear as a foreign body, if the section passes through the enclosing cell. A portion of the protoplasm of the cell may be degenerated and become separated from the remainder of the protoplasm. In many of the rapidly growing epithelial cells of carcinoma there are abnormal processes of nuclear division, and particles of the chromatin may become separated from the nuclei and enclosed in the protoplasm. Even the nuclei of cells may degenerate and take on an appearance very different from the normal nucleus. Entire cells may degenerate, and in this condition they may stain in a peculiar way. There is no doubt that structures are formed in all these ways, and in some cases even normal constituents of the cells have been described as parasites. These supposed parasites have been found in other tissues than the tumors.

The least that can be demanded of those holding the parasitic theory of carcinoma is that parasites must be shown to be always present and to stand in some relation to the pathological processes. The complete demonstration by growth of the parasites outside of the body and innoculation with these alone, can hardly be given. The life history of but few of the protozoa is known, even when the most favorable conditions for their study are present.

From a general consideration of carcinoma there is much which speaks for, and very much against the parasitic theory. Many pathological processes which produce more or less well-defined tumors are known to be caused by parasites. All these formations have much the same character. They usually arise in the connective tissue, and the cells of which they are composed are derivatives of cells belonging to it. They never represent a complicated structure such as we have in carcinoma. There is at first sight some analogy between carcinoma and tubercle, especially in the matter of metastases. In both we have a primary focus, and from this primary focus a material is given off which is carried to other parts of the body and produces a similar growth. There is, however, in the metastases, an enormous difference between the two. No matter what the primary seat of the tubercle, the secondary tubercles are in no way influenced by this. They have the same character under any circumstances. In the case of carcinoma, the secondary nodules are of the same character as the primary nodules. The metastases coming from an adeno-carcinoma of the stomach will present the same typical arrangement of the epithelium as the primary tumor shows, whether they are produced in the lung, muscles, in the liver or elsewhere.

The structure of the primary nodule, moreover, depends upon the character of the epithelium from which it arises. A primary carcinoma of the liver will always present an entirely different structure from a carcinoma arising from the alimentary canal. It proceeds from the epithelium of a part, and in its structure the cells conform more or less to the character and arrangement of the primary epithelium. There is no way of escaping from this fact. Before the development of the parasitic idea it was very generally accepted that the metastases are due to cells of the primary growth, because only from the cells could the more or less complicated structures of the primary

growth be repeated. In the case of tubercle it is different. The metastases there are produced by the bacilli, and the secondary nodule is always of the same structure whatever the seat of the primary. Some of the articles on the parasitic nature of carcinoma are even absurd. The idea has even been advanced that the cells of the tumor itself are parasites. In accordance with this idea a carcinoma arising from the stomach must be produced by a parasite similar in structure to the epithelium of the gastric glands, or in a carcinoma of the liver it must resemble the liver cells, or in a carcinoma from the skin it must have the property of transforming itself into horny epithelium.

A comparison of carcinoma with the tumor-like formations in animals known to be produced by coccidia, as the nodules in the liver of a rabbit, is not justifiable. These formations are simply the result of a hyperplastic growth of the epithelium lining the bile ducts in the form of papillary projections into the dilated vessels. There is no doubt that these growths are produced by the coccidia, and there is no reason why they should not be. If we had metastases from these nodules, if we could have similar tumors with a similar structure formed in the lung from metastases of the coccidia from the liver, the case would be different.

Up to the present time no theory has been advanced which will fully explain the etiology of carcinoma. A theory has recently been advanced by Ribbert that the carcinoma is due to a proliferation of the connective tissue in the vicinity of epithelial growths which penetrates the epithelial tissue. The epithelial cells become loosened from their continuity with one another, and then find favorable opportunity for an unlimited growth in the altered connective tissue. This theory rests on no surer foundation than do any of the others. Probably the theory of Cohnheim, that the carcinoma is due to an embryonic predisposition of the tissues, or to the retention of the embryonic character of the cells in certain places consisting in a power of unlimited growth, still remains the most plausible one.

## THE BILL FOR THE REORGANIZATION OF THE *PERSONNEL* OF THE NAVY.

A BILL with the above title is now before Congress. The efficiency of the navy is to be increased by increasing the number of rear admirals by ten in addition to those at present holding that position, making sixteen; and providing 234 commanding officers for about fifty vessels now in commission. This would undoubtedly be an excellent thing for the officers of the line, providing rapid advancement, and ensuring almost a certainty to those who continued in the service for any length of time of retiring on admiral's half-pay. How the efficiency of the navy would be increased by providing it with so many commanding officers, three-fourths of whom would necessarily be idle at any given time, the bill does not explain. The expense of their support is, however, admitted to be a serious consideration; and how does the bill propose to meet it? By reducing the pay and rank of the staff officers, that is, the surgeons, engineers and paymasters, and at the same time lengthening the time which they are obliged to serve before rank and pay can be increased. The responsibility of the medical and engineer corps of the navy is certainly a great one, and yet the inducements now offered to surgeons proposing to enter the navy are so small that competent men are secured with great difficulty, and the corps has not had its complement since 1865. As the Brooklyn *Eagle* forcibly puts it, "Every diminution in inducement means a lowering of the standard for admission, and under the inducements offered by this bill the standard will necessarily have to be placed so low that the lives of officers and men will be placed in the hands of incompetent persons."

The bill proposes that an assistant surgeon shall enter the navy, with the rank of ensign (corresponding to second lieutenant in the army), and the salary of $1,200 a year. In the army assistant engineers get $1,600 a year, and the rank of first lieutenant. In the navy promotion will be slower. Do the framers of this bill suppose that even men of average ability will enter the navy, and suffer the hardships of life at sea, for $1,200 a year and slow promotion — the highest possible shore duty pay ever attainable, and that after years of service being $3,500 a year? Even the most moderate success in civil life is preferable to such a condition and prospects. The result of the adoption of this bill would certainly mean that only those incapable of taking care of themselves in the struggle for existence on shore would enter the navy, — that is, the incompetent and inefficient. Competent men could not be found to serve under such conditions.

From another point of view the case is well presented by the Brooklyn *Eagle:*

"It has been shown that this bill provides 234 commanding officers for about fifty ships of war. No ship can have more than one commanding officer, but many must have more than one doctor and one engineer. A ship having a complement of 300, 400 or 500 men goes into battle with one commanding officer. If he falls, the next line officer takes his place. It would be inhuman and absurd to send such a vessel to sea in peace or war with one surgeon or one engineer. Even in peace the sickness or death of such men would find no one to take their place. Epidemics on board at sea would find men dying for want of assistance. In war a recent experience has shown how many wounded a few minutes' fight at sea produces. Can one surgeon give the necessary aid? Why, everybody knows that many common surgical operations are never undertaken without several assistants. Can one surgeon do what humanity requires? And suppose the surgeon falls in battle, who is to take his place? No one can, if he is acting alone. It is absurd to say that he cannot fall in battle, that he is down below, safe from shot and shell. In the recent naval battle between the Japanese and Chinese the former lost ten commissioned officers, killed outright, and two of these were doctors – twenty per cent. It is absurd to call any man a non-combatant in these days on a ship of war. . . . Two hundred and thirty-four line officers to command fifty or sixty ships with one commanding officer to each ship! How many doctors? One hundred and sixty-five (Sec. 25), when two or more are required on many ships and the hospitals on shore require staffs. How many engineers?

One hundred and ninety (Sec. 38), when several are required on nearly every ship. How many paymasters? Ninety-six (Sec. 33), for all purposes. Does not this comparison show the line strength in this bill, in which in spite of a number of commanding officers now that cannot be utilized there is an increase of thirty, nearly as many as there are ships, and the medical corps is reduced five numbers — from 170 to 165? Two hundred and thirty-four commanding officers and 165 doctors, 190 engineers and 96 paymasters. Is not this an absurdity?"

From every point of view it is evident that Congress cannot improve the pay and position of the line officer at the expense of the staff without injustice. The bill is rather calculated to decrease than to increase the efficiency of the *personnel* of the navy.

## MEDICAL NOTES.

ACTINOMYCOSIS OF THE LUNGS SIMULATING PHTHISIS.— M. Berard presented to the Society of the Medical Sciences at Lyons, a communication with regard to a case of severe actinomycosis of the lungs simulating advanced phthisis. The diagnosis was made by the examination of the sputum.

A MONUMENT TO HELMHOLTZ. — At the suggestion of the German Emperor, a monument to von Helmholtz is to be erected in Berlin, probably in a public square near the University Buildings. The emperor has promised a contribution of 10,000 marks toward the expense.

A PROFESSORSHIP OF DISEASES OF CHILDREN. — Dr. Otto Heubner, director of the Clinic for Diseases of Children at the Charité in Berlin, has been made a Professor of Children's Diseases. Heretofore diseases of children have been regarded as a side issue at the University of Berlin, and Henoch, the illustrious predecessor of Heubner, was merely an honorary professor.

URINE AS AN AGENT OF ANARCHY.— In a memoir published in the *Révue de Chimie Industrielle*, M. Ackerman points out the use which may be made of urine in the manufacture of explosives. Cyanuric acid which is derived from urine is in fact an isomere of fulminuric acid $C_3H_3N_3O_3$, which is itself a derivative of fulminuric acid, the formula of which is $C_2H_2N_2O_2$. The author of the Latin doggerel beginning "*mingere cum bombis*" probably did not realize the possible direful meaning of his line. Perhaps he would have substituted some other adjective in the second line, so that it should read perhaps instead of "*res saluberrima lumbis*," *res pessima lumbis*.

FURTHER REPORT ON ANTITOXIN. — Soltmann reports (in *Deutsche med. Woch.*, January 24, 1895) 193 cases of diphtheria treated at the Leipzic Children's Hospital between April 1 and December 31, 1894. Of these 50, or 27 per cent. died. During the first four months in which the serum treatment was not generally used, 28 out of 71 children died, or 39.8 per cent.; in the last five months, during which the majority of the children received the serum treatment, 22 out of 122 children died, or 18 per cent. Of this last group of cases 9 out of 33, or 27.2 per cent., not treated with serum died, and 13 out of 89, or 14.6 per cent., of those receiving the serum treatment.

SENATOR GALLINGER ON ANTITOXIN. — The United States Senate has included in an amendment to the Appropriation Bill a sum of $20,000 for a bacteriological laboratory and disinfecting service for the District of Columbia, and for the distribution of antitoxin in the district. Senator Gallinger, of New Hampshire, who is himself a physician, (of the homeopathic school), took occasion to make a speech in which he ridiculed medicine as "the science of guessing." The honorable senator and learned physician then went on to ridicule antitoxin, and say that he soon expected to see it relegated to the tomb of medical discoveries that have been declared worthless if not absolutely harmful. Strange that such ridicule coming from a man who is a United States Senator and at the same time a physician should not have been sufficient to kill the amendment. His words can hardly have had the weight that their author's distinction should carry with them!

A CALL FOR A COLLECTION OF STATISTICS ON SERUM THERAPY IN DIPHTHERIA.— Realizing the importance to our knowledge of serum therapy in diphtheria of the tabulation of a very large number of cases, treated under all possible conditions, as to hospital and private practice, the mildness or severity of epidemics, etc., and the fact that the observations heretofore published have each of them a certain local limitation, and relate to a rather limited number of cases; the editors of the *Deutsche medicinische Wochenschrift* have inaugurated a plan for the collection of statistics on a large scale, embracing the entire German empire. The plan is similar to that which has been successfully employed several times by the *British Medical Journal* for the collection of statistics on important questions. Blank forms have been sent to all the physicians in the German empire, each physician being requested to fill them out and return them to the editors. In this manner the editors hope to be able to collect the results of all cases of diphtheria treated by antitoxin between the present time and April 1, 1895. In this undertaking the editors have the support of such men as Leyden, Litten, Renvers, Heubner, Behring, Ehrlich and Guttstadt. The editors expressly state that they expect from this statistical investigation no definite settlement of the antitoxin question, but hope from the tabulation of the material collected, to give physicians a firmer foundation on which to base their therapeutic use of the antitoxin, and at least temporarily to solve their doubts as to its value.

PERSISTENCE OF THE DIPHTHERIA BACILLUS IN THE THROAT FOR SEVEN AND A HALF MONTHS.— Schäfer, in the *British Medical Journal* of January 12th, reports the case of a boy who had an attack of "tonsillitis" early in last May, which was recognized to be diphtheritic on the occurrence of characteristic paralyses, two months later. Seven and a half months

later two other boys in the same school, one of whom slept in the same dormitory, and the other of whom shared a desk with the May case, came down with diphtheria. A sample of mucus from the throat of the May case was sent for examination along with the others, and was found to contain numerous colonies of typical Löffler bacilli, which on inoculation into animals proved to be active. This is the first instance reported of the persistence of virulent bacilli for so long a period.

Rupture of the Spleen during Coitus. — Harrison gives, in the last number of the *Bristol Medico-Chirurgical Journal*, an account of the autopsy on a lion at the Clifton Zoölogical Gardens. The lion, a fine specimen of his kind, and previously considered perfectly healthy, was found dead in his cage one morning. The autopsy showed an enormous intra-abdominal hemorrhage from rupture of the spleen, which was thought to be undoubtedly due to the exertion of coitus, which had taken place the evening before. The spleen was much enlarged, weighing 21½ pounds, the enlargement, according to Dr. Harrison, being due to increase in the lymphatic and vascular elements. The animal was sick a short time two months before his death, but the symptoms pointed to the thorax. As the death occurred in 1878, before much attention had been called to the value of examination of the blood in these cases, no such examination was made.

Gastrostomy for Foreign Bodies. — At a recent meeting of the Leeds and West Riding Medico-Chirurgical Society Mr. Mayo Robson read an interesting paper upon a remarkable case of foreign bodies removed from the stomach of a child by gastrostomy. The patient was ten years of age, and had been admitted into the hospital for gastric symptoms which were not of a very definite nature. For eight months the symptoms had persisted without yielding to any treatment. However, while under observation in the hospital the patient vomited a nail. It was then decided to open the stomach, and as a result of the operation the following curious collection of heterogeneous objects were removed: 47 cast-iron garden nails, 1⅝ inches long; 93 brass and tin tacks, ½ inch to 1 inch long; 12 large nails, some brass-headed; 3 collar studs, 1 safety pin, 1 sewing needle. All these, of course, had during the previous eight months been swallowed by the child. The operation wound healed by first intention, the patient making a complete recovery.

Bacilli Tuberculosis in Cigars. — Dr. Kerez (*Centralblatt für Bacteriologie*) reports the result of experiments which he has been making for the purpose of determining the possibility of the communication of tuberculosis through the medium of cigars. It is a well-known fact that cigar-makers are in the habit of making the leaves adh ere to the cigars by moistening them with saliva from their own mouths. The force of habit leads them to continue this practice, although in recent times manufacturers provide their workmen with materials for the purpose indicated. Dr. Kerez made cigars by moistening the leaves with saliva known to contain tubercle bacilli. The cigars were then dried and packed away in boxes in the usual manner. It was found afterward, when the cigars were unrolled and the leaves washed in water, that the infusion thus obtained, having been injected into guinea-pigs produced tuberculosis, clearly showing that cigars may thus be the means of communicating tubercle bacilli and giving rise to pulmonary disease. — *La Médecine Moderne.*

## NEW YORK.

Death-Rate of New York City. — During the week ending February 2d, there were reported 952 deaths in the city, an increase of 19 over the preceding week. There were 203 deaths from pneumonia, 71 from influenza, and 33 from diphtheria.

Bequests for the Home for Incurables. — The Home for Incurables, which is situated at Third Avenue and 184th Street, has recently received two bequests, one of $70,000 and one of $10,000, and the money is to be devoted to the erection of a large new wing to the hospital.

Electrical Execution. — In the case of the negro murderer, David Hampton, who was executed by electricity at Sing Sing prison on January 28th, the autopsy showed considerable ruptures of the cerebral arteries as a result of the current. Any attempt at resuscitation in this instance at least would therefore have proved fruitless.

Damages for Death by Accident. — Under the old Constitution of the State the limit for damages recoverable for death by accident was placed at $5,000, but under the amended Constitution there is no limit to such damages. On January 30th $18,000 was awarded by a jury to the widow of Terence C. O'Reilly for the death of her husband, who was killed by a mail wagon; this being the first case of the kind since the new Constitution went into effect.

Death of Dr. Ostrander. — Dr. Ferdinand W. Ostrander, who had the reputation of being the oldest practising physician in Brooklyn, died at his residence in that city on January 30th. He was born in New York on June 4, 1804, and at the age of twenty-three was graduated from the College of Physicians and Surgeons. For the past ten years the greater part of his practice has devolved upon his son, Dr. John W. Ostrander. All his professional career was spent in the city of Brooklyn, and he was at one time health officer there.

Prevalence of Pneumonia. — Pneumonia continues to be very prevalent and fatal, a large proportion of the cases no doubt resulting as a sequence of influenza. During the week ending January 26th, out of a total mortality of 933 in the city, no less than 199 were due to this disease. In a recent report Dr. John T. Nagle, Registrar of Vital Records, in pointing out the increase of pneumonia during the last four years, states that in the year 1830, when there were 5,498

deaths in the city, only 228, or 1 in 22.8 were due to this cause; while in 1893, when the deaths numbered 44,486, 6,487, or 1 in 6.86, were from pneumonia.

THE NEW YORK COUNTY MEDICAL ASSOCIATION. — At the recent annual meeting of the New York County Medical Association, Dr. S. B. W. McLeod was re-elected President, Dr. A. D. Ruggles, Vice-President, Dr. P. Brynberg Porter, Recording Secretary, and Dr. John H. Hinton, Treasurer. Dr. N. G. Bozeman was elected Corresponding and Statistical Secretary, and Dr. Thomas H. Burchard, member of the Executive Committee. The report of the Statistical Secretary showed that during the year 105 new members had been elected and that there were now upon the roll of the Association 1,006 active members.

DR. A. L. LOOMIS'S WILL. — By the will of the late Dr. Alfred L. Loomis the income of $25,000 is given to the Loomis Laboratory, and whatever part of the income is not used is to be paid to the professor of pathology and practice of medicine in the University Medical School. To the New York Academy of Medicine is left $10,000, the bequest to be known as the Loomis Entertainment Fund, and the interest to be used in providing entertainment for the Fellows of the Academy. His medical library is left to his son, Dr. H. P. Loomis. The total value of the real estate is placed at $400,000 and of the personal property at about $600,000.

## Miscellany.

### CREDIT SIDE OF THE CHOLERA ACCOUNT.[1]

A REDUCTION of more than fifteen per cent. in the general death-rate is, grossly stated, the claim made for the sanitary administration of Great Britain initiated by Sir John Simon in 1865, when he undertook the defence of that country against Asiatic cholera. Abandoning *in toto* the system of defence by quarantine restrictions, as against that individual disease, a vast machinery of notification, isolation and disinfection with reference to the infectious and contagious diseases generally, has been organized, the efficiency of which may be measured, with substantial accuracy, by the statistics of one group of diseases — the typhoid or enteric and other continued fevers. Thorne-Thorne has recently shown that, whereas the mean annual death-rate of this group was 567 per million living in the five years 1869–73, it was only 179 in the five years 1888–92; that if, during this latter quinquennium, people had died of these fevers at the rate at which they died in the former five-year period, there would have been during 1888–92 no fewer than 55,808 more deaths than actually occurred; and that had the same mortality obtained in 1892 that prevailed in 1869 no less than 14,232 persons who, at the end of 1892, had escaped death from these causes, would have died during that year. "In short," he says, "even if cholera had recurred in England and Wales between 1867 and 1892 — a period during which that disease was practically absent from our midst — on the same scale as between 1849 and 1866, we should still be the gainer by several hundreds of thousands of human lives. And our gain in this respect is largely due to the incentive given by reason of cholera prospects and of the knowledge that the disease would have to be met by improved sanitary administration."

### CONGENITAL PHIMOSIS.

THE following account of a case of congenital phimosis appears in a recent number of the *Southern Practitioner* (October, 1894): "It is remarkable," says the writer, "for the length of time the patient has been subjected to symptomatic medication without regard to the obvious cause of the trouble." It is equally interesting for the secondary effect of the phimosis upon the *lingua* of the writer.

J. H. W., age nineteen, a machinist by occupation, sought advice in relation to his *vita sexualis*, August 4, 1894. Examination revealed an extreme degree of phimosis, the foreskin being long, redundant, and flabby, with a hair-like orifice at the extremity. The integument being involuted, passed back an inch or more, when it joined the mucous membrane in such a manner as to form a complete *cul-de-sac* of considerable dimensions. Into this *plica abnormalis* the patient passed his urine, it having a sufficient capacity to hold the entire quantity of urine voided at one time. After urinating the patient had to milk or squeeze the urine out of the *cul de-sac* with his fingers, so small was the orifice.

Urine could be passed when the bowels acted only. The general health had never been good, and the patient complained of many functional disorders, such as palpitation of the heart, constipation, indigestion, nervousness, insomnia, vertigo, night emissions, erotic dreams of men, great exhaustion, lack of energy, anemia, insufficient self-confidence, both mentally and morally, and perverse sexual instinct.

We quote *verbatim et literatim* the remainder of the history:

"Patient attempted coitus once two years ago with a *puellæ publica*, but did not have *immissio penem* in vagina, and becoming disgusted with *femmes*, never repeated the attempt, but practised mental onanism occasionally by imagining the *cul-de-sac terminalis* to be a vagina in *puellæ pulchra*, had ejaculation in from two to five minutes, the semen lodging in the *plica abnormalis*, and squeezed out through the small opening per *manum* subsequently. In his dreams he always played the role of *femina*, and *vice versa* when awake. His *libido* had been intense as far back as he could remember. Diurnal involuntary erections occurred repeatedly, but not followed by ejaculation unless he thought of *puellæ pulchra*."

A circumcision resulted in a complete restoration to health and to the vernacular.

### STEAM AS A HEMOSTATIC.

PROF. W. F. SNEGIREW,[2] of Moscow, reports the successful use of steam for hemostatic purposes in several cases where other means have been unsuccess-

[1] Journal of the American Medical Association.
[2] Deutsche med. Woch., No. 38, 1894.

ful or inconvenient. His attention was first called to the possibility of using steam as a general hemostatic, as the result of a severe hemorrhage occurring during an operation on the liver. On reading the literature of hepatic hemorrhage he was impressed, he says, by the general helplessness of the surgeon in such cases. "Even the actual cautery was not always sufficient, and in most cases required the additional aid of a closely placed tamponade of gauze."

For some time Professor Snegirew had been in the habit of using steam as a cauterizing and hemostatic agent in the treatment of uterine disease, in the following manner: After dilating the uterine canal an application of steam was made through a small metal tube enclosed in a catheter. After a half or at most a full minute of this application, a dark fluid, with a strong brothy odor, returns through the catheter. In his experience there has been no pain attending this application and many cases of tender, painful, bleeding conditions of the uterine mucosa have been entirely relieved.

Carrying out the suggestion from this use of steam he conducted a series of experiments with Dr. Blagowolin, to determine the hemostatic value of steam upon the liver and other organs. Their results in animals were as follows:

(1) They were enabled to remove without loss of blood such sized pieces of the liver as they chose, the animal surviving.

(2) Similar results were obtained on the spleen.

(3) They removed entire lobes of the lung without hemorrhage.

(4) Considerable sized pieces of kidney were successfully removed.

(5) From the brain, excision of pieces up to a limited size.

(6) Bleeding from the spongy portions of bones was stopped.

(7) The marrow was scalded, but the restoration of the bone went on as usual.

(8) The femoral artery of a dog, cut through either across its course or lengthwise, did not bleed under the application of steam.

(9) The wounds after the use of steam healed by primary intention in animals, and also in men upon whom it was used.

As the result of these experiments, steam was used as a hemostatic during the past summer in the Alexiner Semstwo Hospital with success in the following operations:

(1) In five cases of resection of the knee-joint, without elastic bands, ligatures or artery forceps.

(2) In the extirpation of a cancerous breast, under the same conditions as above; also in the removal of fatty and malignant new growths in the skin.

(3) In amputation of the cervix uteri and in fibromyotomy.

(4) In resection of bone and in removing sequestra.

(5) In abscesses, to render them odorless and induce rapid healing.

(6) In fistulæ and sinuses, especially when tubercular.

There seems little doubt in the minds of the investigators that in steam they have found a hemostatic of ready usefulness, aseptic, not interfering with primary union, and above all applicable to parenchymatous organs, such as the liver. Certainly further reports will be eagerly awaited.

## THERAPEUTIC NOTES.

For the Vomiting of Pregnancy. — The following is from the *Practitioner*:

℞ Menthol . . . . . gr. xl
Olei Amygdalæ . . . . . ʒ iij
Solve. Six to ten drops on a lump of sugar.

The Treatment of Diphtheritic Laryngeal Stenosis. — Brenner Berent[1] has in two cases seen remarkably good results follow painting with cantharidal collodion of a spot the size of a half-dollar over the thyroid cartilage.

Sterilization of Knives for Surgical Purposes. — In the *Archiv. für klinische Chirurgie* (48, 4, Berlin, 1894), Ible states that knives can be rendered aseptic by boiling in one-per-cent. soda solution, without affecting in any way the sharpness of the edge. The manner in which this dulling ordinarily takes place is that the edges are dulled against the sides of the boiler or the other instruments. He proposes a small knife case to be boiled with the instruments. As soda crystals consist of 75 per cent. of water of crystallization, it is necessary in order to obtain a one-per-cent. solution to employ at least three tablespoonfuls to the half litre of water.

Deaths reported 2,955: under five years of age 923; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 289, acute lung diseases 619, consumption 345, diphtheria and croup 148, scarlet fever 38, typhoid fever 38, diarrheal diseases 25, whooping-cough 16, cerebro-spinal meningitis 12, measles 11, erysipelas 5, small-pox 1.

From diarrheal diseases New York 7, Philadelphia 4, Boston 3, Brookline 2, Cincinnati, Lynn, Springfield and Taunton 1 each. From whooping-cough New York 4, Brooklyn 3, Philadelphia, Boston and Washington 1 each. From cerebro-spinal meningitis New York 4, Washington 3, Cleveland and Lynn 2 each, Worcester 1. From measles New York 4, Philadelphia and Boston 2 each, Brooklyn, Worcester and Haverhill 1 each. From erysipelas New York 2, Philadelphia, Brooklyn and Boston 1 each. From small-pox New York 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530, for the week ending January 19th, the death-rate was 21.7. Deaths reported 4,407: acute diseases of the respiratory organs (London) 399, measles 96, whooping-cough 66, diphtheria 63, diarrhea 49, fever 36, scarlet fever 25, small-pox (Birmingham 2, London 1) 3.

The death-rates ranged from 12.9 in Plymouth to 33.4 in Wolverhampton; Birmingham 27.9, Bolton 29 3, Bristol 21.9, Burkley 26.2, Huddersfield 22.0, Leeds 24.9, Leicester 15.1, Liverpool 28.3, London 20.0, Manchester 23.3, Newcastle-on-Tyne 21.2, Nottingham 22.9, Portsmouth 20.6, Sheffield 22.7, Sunderland 30.7, Swansea 21.0, West Ham 18.4.

## METEOROLOGICAL RECORD,

For the week ending January 26th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer | Thermometer. | | | Relative humidity. | | Direction of wind. | | Velocity of wind. | | W'th'r.* | | Rainfall in inches. |

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 26, 1895, TO FEBRUARY 1, 1895.

The extension of leave of absence on account of sickness, granted FIRST-LIEUT. HENRY R. STILES, assistant surgeon, is still further extended two months on surgeon's certificate of disability.

## OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SIXTEEN DAYS ENDING JANUARY 31, 1895.

AUSTIN, H. W., surgeon. To proceed to New Bedford, Mass., as inspector. January 18, 1895.

## HARVARD MEDICAL SCHOOL.

### EVENING LECTURES.

The next lecture will be given on Thursday evening, February 14th, at 8 o'clock, by Asst. Prof. M. H. Richardson. Subject, "The Operative Surgery and Prognosis of Mammary Cancer." Physicians are cordially invited.

## RECENT DEATH.

LEVI PILLSBURY, M.D., M.M.S.S., died in Fitchburg, February 4, 1895, aged seventy-seven years.

## BOOKS AND PAMPHLETS RECEIVED.

Electro-Therapeutics in the Practice of Dermatology. By Richard B. Faulkner, M.D., Alleghany, Pa. Reprint. 1894.

Astigmatism as a Factor in the Causation of Myopia. By Leartus Connor, A.M., M.D., Detroit, Mich. Reprint. 1895.

Intraligamentous and Retroperitoneal Tumors of the Uterus and its Adnexa. By William H. Wathen, A.M., M.D. Reprint. 1894.

Modern Homeopathy, Its Absurdities and Inconsistencies. By William W. Browning, A.B., LL.B., M.D., Brooklyn, N. Y. Reprint. 1894.

The Code Question from the Standpoint of a General Practitioner. By D. A. Robinson, M.D., of Bangor. Portland: Stephen Berry. 1894.

Thirty-ninth Annual Report of the Trustees of the Northampton Lunatic Asylum for the year ending September 30, 1894. Boston: Printed by the State. 1895.

The Relation of Static Disturbances of the Abdominal Viscera to Displacements of the Pelvic Organs. By J. H Kellogg, M.D., Battle Creek, Mich. Reprint. 1894.

A Surgical Kit Containing all the Essentials for Aseptic Operations at Private Residences. By Reuben Peterson, M.D., Grand Rapids, Mich. Reprint. 1894.

Ligation of the Internal Jugular Vein for Profuse Hemorrhage caused by a Sloughing Adenitis, which followed Malignant Scarlet Fever. By Lewis H. Adler, Jr., M.D. Reprint. 1891.

Ueber eine Färbemethode, mit der man Diabetes und Glycosurie aus dem Blute diagnosticiren kann. Von Dr. Ludwig Bremer, St. Louis, Mo. Sonder-Abdr. a. d. Centralblatt f. d. med. Wissenschaften, 1894, No. 49.

Hygiene of the Eye. Evisceration of the Eye-Ball. Immediate Capsulotomy following the Removal of Cataract. An Introductory Address to the Students of the Medico-Chirurgical College. By L. Webster Fox, M.D., Philadelphia. Reprints. 1894.

Las Inflamaciones Pelvianas de la Mujer y su Tratiamiento Racional segun la Clinica. (Comunicacion al XI Congreso Internacional de Medicina, Roma, 29 de Marzo, 1894.) Por el Dr. D. Celestino Martin de Argenta, Director de una Clinica ginecologica y Profesor libre de Ginecologica a Salamanca. Madrid. 1894.

Ueber Tubarschwangerschaft und die Behandlung der Blutungen in die Bauchhöhle infolge von Tubarschwangerschaft. Ueber die Behandlung der Placenta Prævia mittels intrauteriner Kolpeuryse. ## MEDICAL TREATMENT IN DIPHTHERIA.[1]

BY A. L. MASON, M.D.,
*Visiting Physician, Boston City Hospital.*

In a brief consideration of the medical treatment in diphtheria, which I have attempted at the request of your President, by way of introducing a general discussion on that subject, I will ask your attention to the more serious questions relating to that disease as they have presented themselves clinically in an experience of twenty years, during the latter part of which period my colleagues and myself at the Boston City Hospital have had under our charge annually a very large number of cases, many of them of the worst description.

While the recently proclaimed success of the treatment of diphtheria by the antitoxin may almost render it superfluous further to discuss the plodding methods by which we have so long struggled with this disease, still it may not be unprofitable to defer an opinion as to the rôle in therapeutics which this great discovery is destined to play, and by a study of past results to form an estimate of the many dangers which this new agent will be expected to overcome.

From 1880 to 1889, 1,300 cases of diphtheria entered the hospital; and in more recent years the admissions have been 300 or 400 annually. About one-third have required tracheotomy or intubation, and the great mortality in cases of respiratory obstruction is practically uninfluenced by any medical treatment hitherto at our command. Exclusive of those cases which have needed surgical interference, the death-rate in those requiring medical treatment alone has been 25 per cent.; nearly double that rate, however, for the whole series.

Without entering into the details which explain the terrible fatality of diphtheria in all communities where it is endemic, as during the last fifty years it has become in most of the large cities of Northern Europe and America, it may be said in brief that the disease often makes fatal headway before its character is recognized; and that the absence of coöperation on the part of most of the subjects, owing to their tender years, throws special difficulties in the way of successful treatment by the measures heretofore adopted. The simple injection of a fluid will, of course, entirely do away with this latter difficulty.

Passing by the milder forms of tonsillar diphtheria, which get well under almost any treatment, in the severer types, with extensive faucial, nasal or tracheal exudate and glandular swellings, there is a threefold danger to life, namely, through septic exhaustion, tracheal obstruction, and the various complications and sequels, of which the most serious are broncho-pneumonia, acute nephritis and toxic paralysis. Dysphagia may, from the outset, cause grave difficulty in nutrition.

What then are our means of contending with or of averting these conditions? Can we prevent septic absorption or overcome profound sepsis after it has developed? Can we stop the extension of membrane to the larynx, trachea or bronchi? Can we ward off pneumonia, acute nephritis or paralysis? Or can we cure these complications when they arise?

The answer to most of these questions must, in the light of past experience, be negative; and so it will be in the future with regard to many cases coming late to treatment. With a disease sometimes so treacherous and virulent, and at others so mild as to escape notice, it is useless to dogmatize about this or that special therapeutic measure which may, from time to time in a limited number of cases, be attended by favorable results above the average.

Until the present year those physicians whose experience and observation have been the most extensive were unable to claim any great degree of success in contending with the worst types of diphtheria. In spite of the most assiduous efforts, its ravages have remained practically unchecked. Many bad cases, and some which appear almost hopeless, respond to the general and special measures which are adopted, but we have had no confidence in such a successful result.

The indications for treatment are clear, and point to such measures as will save and maintain the strength of the patient, with the discriminating use of those local applications which tend to check or neutralize toxic absorption and to prevent invasion of the respiratory tract.

In the maintenance of the strength which so rapidly fails in this disease, not only is the ingestion of a sufficient quantity of easily digested food essential, in a shape which can be best swallowed, but the wasting of the vital forces by too much painful and exhausting treatment must be avoided. Vierordt in his "Medical Diagnosis" says, "In diphtheria immediate death may follow an effort to examine the throat."

Tincture of the chloride of iron, oxygen and alcohol, in large doses, have met with professional approval to correct toxemia and to sustain the flagging heart. They are doubtless serviceable in many cases *not* of the most septic type, but in the latter, absolutely ineffectual. The same is true of strychnia, strophanthus and digitalis. Internal antiseptic drugs have not proved beneficial.

Early difficulty in swallowing may be the result of simple pain or of paralysis. Regurgitation through the nose attends the latter condition, and may occur in the first week. Care must then be exercised in the administration of food and medicines, both on account of the distress which the patient experiences in his efforts at deglutition, and the danger of strangling, or of broncho-pneumonia from the entrance of food into the air-passages, the so-called deglutition-pneumonia. Choking may be fatal as in the following instance reported to the Clinical Society of London by Dr. White last February: A patient with diphtheritic paralysis, while drinking a cup of tea, was seized with cough, spasm and dyspnea. He died, and at the autopsy an ounce and a half of tea was found in the bronchial tubes. There was no other cause for the sudden death.

Nutritive enemata may partially obviate this difficulty in the adult, but they are seldom well retained by young children. Systematic feeding by a soft catheter passed through the nostril into the gullet sometimes saves life. I have seen recovery in the case of a child with complete faucial paralysis who for four weeks could be fed in no other way. Dr. W. A. Morrison, at the Suffolk District Society last year, related several cases successfully treated in this manner.

### LOCAL TREATMENT.

In the use of topical sprays or lotions, it must be asked, Have we any agent on which we can depend to arrest the disease or to prevent the extension of mem-

[1] Read at a meeting of the Boston Society for Medical Improvement, November, 1894.

brane to dangerous localities? It is not improbable that success would oftener attend our efforts in this direction if cases were seen at an earlier stage, but in those which have already become malignant, in which the membrane spreads with great rapidity, nothing at our command has thus far been able to avert septicemia or croup with any degree of certainty whatever.

In the use of local remedies there is great room for choice and for individual judgment as to the mode and frequency of their application. Their effect upon the patient must be carefully observed, the amount of pain which they cause and the degree of fatigue which follows. Great exhaustion not uncommonly ensues in patients whose hearts are already weakened, therefore it is evident that in such cases, especially with young and frightened children, it is best to make the intervals less frequent and to use the milder and less painful cleansing agents. Physicians have recommended an almost constant spraying and swabbing of the nose and fauces, every half-hour, day and night. Such zealous measures, except for very brief periods, exhaust the child and wear out the nurses. Force is objectionable, but its judicious use may be necessary in young subjects. In patients with pallid countenance and feeble pulse, no treatment which obliges them to sit up is permissible. Irrigation with the douche bag can be resorted to in the recumbent position. Sleep, fresh air and an abundance of drinking-water are of the first importance. Plain or medicated steam, so often used for impending croup, is of doubtful benefit and the heat is uncomfortable.

Of the many detergent and antiseptic remedies for cleansing and sterilizing the nose and fauces, I will mention but few, as, one after another, the more powerful and painful agents have been generally abandoned as useless or harmful. Mild carbolized sprays, such as Dobell's, lime-water, warm alkaline solutions, chlorine-water, and peroxide of hydrogen, may be used, the latter in a ten- or fifteen-volume solution, or stronger, once or twice daily for a few days for the removal of membrane. It has a perceptible effect upon the exudate, but is sometimes painful, and I think its prolonged use is more irritating than the other substances mentioned. Its germicidal effect must be considered, and in this respect I have also thought swabbing twice a day with corrosive sublimate, 1 to 5,000 or 10,000, valuable. Mercurial poisoning may occur. This is an objection to the free use of corrosive sublimate inhalations from the steam atomizer. A saturated solution of boracic acid is often used. Cocaine mitigates the pain of local applications.

With these measures we see many bad throats, and a few of the worst clear up and recover, even after a moderate degree of sepsis has developed, and most certainly the employment of active antiseptic measures in a prudent manner, is and always will be a requisite in the management of the throat affection in diphtheria, not only with reference to the Klebs-Löffler bacillus, but also to the streptococci and staphylococci which add so much to the danger. But they do not reach far enough.

The disinfection of the nose is most difficult, both on account of pain, when forcible spraying is resorted to in the swollen and almost impervious condition of the nostrils, and from the inflammation of the frontal sinuses and middle ear caused by too zealous attempts to cleanse the nasal passages by the douche or atomizer. Therefore, I have formed the opinion that, in young children especially, the blandest fluids, at a warm temperature, by the force of their own gravity only, should be used in the nose. Adults may use the warm saline douche, or a very weak solution of peroxide of hydrogen, cautiously.

Again, we may see the throat clear up satisfactorily and the glands subside while the disease is making insidious progress in the windpipe and bronchi. Then the expulsion of a "tree" of ramifying membrane sometimes gives warning of the end, for in such extensive involvement of the bronchial tubes recovery is a rare event.

Broncho-pneumonia and nephritis we cannot prevent, and they occur in a large proportion of cases. The nephritis, being of an acute infectious type, tends to recovery in those cases which survive the general malady, but convalescence is often slow and albuminuria may persist for many months. There is danger of exacerbations from errors of diet, fatigue, or undue exposure.

In a few septic cases there is an uncontrollable hemorrhagic oozing from the mucous membrane of the mouth, nose or pharynx, and rarely petechiæ occur. I have never seen one of these cases recover.

Especial difficulties sometimes arise in the management of diphtheritic paralyses. I have already alluded to the early deglutition symptoms which may complicate bad cases, and in the same way there may be, in the first week, dangerous impairment of the cardiac function, probably pneumogastric in origin, since frequent vomiting is an attendant symptom. No doubt, too, the heart is the seat of septic invasion, which causes degeneration of the myocardium, in most cases of diphtheria. In a series of several hundred cases, a German writer (Hoppe-Seyler) found cardiac symptoms in one-half, and manifest fatty changes at most of the autopsies.

The effect of the diphtheritic toxines, however, in causing paralyses, is not usually a sudden one, but gradual and cumulative, after the active manifestations of the disease have ceased. Different sets of muscles may be invaded in turn according to no apparent rule. It is then that the persistence of a rapid, feeble pulse and a pallid face, excite apprehension of heart failure, and indicate the necessity of absolute repose and the utmost care to avert a fatal issue. A galloping rhythm, from asynchronous contraction of the ventricles, sometimes gives warning before the heart's action becomes rapid. Recovery is slow and there is often continued precordial pain and oppression. Such patients should be watched until the knee-jerk returns. I have recently observed a case for several weeks in which the muscles of the throat, legs, arms and eyes were involved, as well as the heart and respiration. It has not seemed to me that the usual cardiac tonics, such as digitalis and strophanthus, or even strychnia, are of much avail in this state. Alcoholic stimulants by the mouth, rectum, or subcutaneously have been of service in some cases of repeated collapse due to this condition, and the electric battery may be tried. Free elimination of the toxines, however, through the skin, bowels and kidneys, is quite as important as urging the heart and nervous centres to increased action.

In a former paper (1893) relating to the advantages to be derived from the opening of the New Hospital for Contagious Diseases, I ventured to say that it was not too much to expect that improved methods, especi-

ally as applied to the early stage of diphtheria, would result in a greater proportion of recoveries. We were not then aware of the extent of the antitoxin experiments which were going on in France and in Germany. In spite of the skepticism engendered by previous serotherapeutic failures, and the commercial competition which the new remedy has excited, the evidence presented by Roux, Behring and others is so detailed and complete that a general feeling of hope and belief has arisen that the enormous mortality from diphtheria will soon be a thing of the past.

[Note. — During the last two months the mortality in 100 cases treated at the City Hospital by the antitoxic serum has been 14 per cent. These cases were mostly in the service of Dr. Withington and were of severe type.]

## MEDICAL TREATMENT OF DIPHTHERIA.[1]

BY E. M. BUCKINGHAM, M.D.,
*Visiting Physician, Boston City Hospital; Instructor in Diseases of Children, Harvard University.*

In discussing the treatment of diphtheria the first question that presents itself is whether we shall treat it at all, or whether we shall decide that it is too dangerous, and shall therefore abandon it entirely to men without practice and without families, that is to say, give up the treatment of one of the most serious diseases known, to young men without experience. If this is really necessary it must be done; and if it is unfortunate for diphtheria patients, so much the worse for them. But in forming such a decision, which I think is a wrong one, we should be governed by reason and not by panic, that is to say, not by blind, unreasoning fear. If by study of the means by which contagion is spread, we can learn to take intelligent measures against it, and render it safe to go from diphtheria anywhere; then we are able to widen our sphere of usefulness and perform a duty which we owe to those who trust us with their health and lives.

Every one knows that under some circumstances diphtheria can be carried by mediate contagion. Of course, clothing or hands may be infected by contact with the patient; and there is positive evidence that clothing once infected may under suitable conditions retain the poison for a long time. On the other hand, there is, so far as I know, no evidence whatever that it floats about in the air, while there is certainly much evidence to the contrary. It is impossible for me to give all the evidence, much of it forgotten, that during a long service in the diphtheria wards has crystallized this belief into my mind; and it is not the intention of this paper to go beyond personal experience. I might cite cases of tonsillitis that have been sent to the City Hospital with the diagnosis of diphtheria, and have, of course, been admitted to the diphtheria service. After a proper period of observation very many such cases have been decided not to be diphtheria and have been discharged without contracting it, although breathing the air of the ward for days.

On one occasion last winter having made a two hours' visit, accompanied by two internes, a nurse and seven students — ten in all beside myself — an ample number to stir up whatever dust might be free, — I went directly to the laboratory without going into the open air, and had cultures made from my pantaloons. New pantaloons were worn on this occasion in order that they might not be filled with street dust. These cultures were made from cotton that had been rubbed over the lower part of the leg, especial attention being paid to the inner surface where it slides on the boot. These cultures were examined by Dr. Wright with great care and with negative result so far as the diphtheria bacillus is concerned. I do not mean that there are no diphtheria bacilli on the floor. I know[2] that there are — sheets, etc., must occasionally touch the floor; but for a single severe practical test as to the danger of carrying contagion from the ward, this appears satisfactory. On another occasion I had my moustache examined — I think by Dr. Cumston — after spending a long time in personally examining nearly every throat in the wards. Numerous streptococci were found but no diphtheria bacilli. One would expect these results from the way in which these bacilli will often adhere to definite places for weeks, without invading neighboring parts. Thus they will be found on the tonsil but not in the nose, or *vice versa*, or membrane will remain in the larynx visible with the aid of the laryngoscope for long periods, during which the bacilli are not found elsewhere.

In order at once to illustrate the immunity with which the air of these wards can be breathed so long as contact is avoided, and to show what can be accomplished with the aid of antiseptics, let me report two cases.

Last winter a woman was admitted with supposed pseudo-diphtheria — a case that I shall not report in a collection of pseudo-diphtherias that I am making, because of a possible doubt as to the diagnosis. She had a syphilitic eruption, alopecia, and warts on the vulva. There was a mucous patch under the tongue; and while the appearance of the throat was that of diphtheria in the opinion of the admitting physician and of several of my colleagues as well as of myself, yet as the bacilli of diphtheria were never found, there might be a doubt in the minds of some who had not seen her. The day after admission this woman was delivered of a child in the ward. Dr. Stevens, the senior interne, attended to the confinement, giving a corrosive vaginal douche (1 to 1,000) before and after birth, and cleaning his hands with soap and water, then corrosive sublimate, and then permanganate of potash followed by oxalic acid. Of course, he paid particular attention to his nails. He must have had recently infected hands, as he had done several intubations within a short time; but his precautions were sufficient, for numerous cultures from the vagina at various times afterward, failed to show the presence of diphtheria bacilli. The woman stayed in the ward, and was attended by diphtheria nurses, who always corrosived the hands before touching her. She wore an antiseptic pad. The baby was nursed by the mother, and cultures from its mouth and nose were always negative. That this might be done safely, the child was kept in a basket and never touched by the mother, while the breast was disinfected with corrosive sublimate before each nursing. Had I thought that the mother had true diphtheria, and had I not known that she had syphilis, I should probably have taken a different course on her account.

Another woman, with true diphtheria complicated with lobar pneumonia, was delivered in the ward at

[1] Read before Boston Society for Medical Improvement, November 26, 1894.

[2] Wright: Centralblatt für Bacteriologie, 1894.

eight months. This labor was in charge of the junior interne, Mr. (now Dr.) Waughop. An hour and a half was spent in resuscitating the child which had swallowed large quantities of amniotic fluid. It was then isolated in the ward as the other had been, and was fed from a bottle for two weeks, owing to the neglect of its friends to send for it. Notwithstanding its remarkable history, numerous examinations failed to find diphtheria bacilli in its mouth or nose. The course of the mother's disease, unfortunately gave us no opportunity to make cultures from the vagina. Dr. Waughop's precautions were soap and water and corrosive sublimate. Here, again, was an extremely good chance for infection, and the greatest credit belongs to both of these gentlemen, and to the nurse Miss Tirrell, all of whom must have infected their hands again and again every day, but all of whom were careful to disinfect.

Since the construction of the present diphtheria building, I have had service in it every year but one, in terms of one, two or four months; and while constantly watchful, I have never had reason to suspect that I had carried diphtheria from it to any one. During the present year I had a four months' service, the wards being uncommonly crowded;[2] and although I was attending to my usual patients and was seeing a fairly large number of children at the time, it so happened that only once did I see diphtheria in any one whom I had been near for many weeks. Indeed, I saw very little diphtheria among private patients. That once was the case of a child who had been in the room when I examined her sister on a single visit a week before, and who had been exposed at school since.

If this can be true of a man who is spending from one to three hours a day, oftener three than one, in the largest collection of diphtheria in the country (unless it be at New York), perhaps it follows that his methods of disinfection are sufficient. They are intelligible if one believes, as I do, that this disease is carried by contact, either direct or indirect, and that it does not appreciably float about in the air. (1) A clean linen cap and coat were worn while in the ward; both, I believe, unnecessary if one will be sure that neither his own infected hands, nor the patient, nor anything touched by the patient, or that has been touched by the nurse comes in contact with his dress or face or hair. (2) The sole of the boot was disinfected with corrosive sublimate after leaving the ward. (3) The hands and wrists were soaked, not merely wet, in corrosive sublimate, 1 to 1,000. (4) This solution was allowed to dry into the skin, unless a towel was at hand that had been touched by no one in attendance on the patients.

Leaving the treatment of the physician and coming to that of the patient, I may say that personal experience, so far as it entitles me to form an opinion, would lead me, at present, to give a better prognosis in cases in which the diphtheria bacillus is absent than in those in which it is present. In some twenty cases that came under my care last winter there were no deaths, and generally they made early recoveries. It is my impression that the same is true of my previous term.

Diphtheria in which the bacillus is found, begins, as a rule, very gradually. I have made particular inquiry with regard to this point in about half the adult cases that came into my service last winter. All had been at their accustomed employment for one, or two, or more days, sometimes many days, after the beginning of sore throat or other symptoms of disease, such as coryza or malaise. Nevertheless, at the time of coming under observation, the circulation was always poor. I do not recall any exception. This poor circulation, which continues until convalescence is well established, is often manifested not so much by change in the rate of the pulse as by its compressibility. It is also shown by the slow return of color when it has been pressed out of the hands. This last is a very common symptom. Therefore, I am in the habit of giving stimulants from the beginning, often with a small initial dose, but knowing no upward limit until the pulse is strengthened, or on the other hand, intoxication or permanent smell of brandy are reached. I cannot recall more than one case of intoxication, but a permanent smell of brandy is a danger-signal that I have known to be followed by vomiting when its warning has been disregarded. Some patients can take surprisingly large amounts. The most extreme case that I recall was a girl of seven years with septic diphtheria, who took twelve ounces of brandy per day, with no apparent effect except to keep her heart beating. Of course, such cases need careful watching. Digitalis and strychnia have, I am sure, a valuable place in enabling us to keep the dose of alcohol within the limits of the stomach's tolerance. Rather to my surprise, the effervescence of champagne does not irritate the sore throat in all cases.

Since the disease is so exhausting, feeding is an important part of its treatment, but it is sometimes difficult on account of intense soreness in swallowing. Ice cream, iced milk, or iced milk and brandy mixed with a cobbler-shaker or an egg-beater, have enabled me to give much more food than I could have given without them. Rectal enemata have a place; and twice last winter, when the rectum failed to retain these, I have ordered liquids to be administered to a little child by means of a soft catheter into the stomach. Both children died. In one case the house physician exercised the discretion allowed him by stopping treatment, as the child was failing in spite of it. It is, I think, a cruel treatment, only to be resorted to in emergency. Even then, if there is great resistance, perhaps by exhausting the strength, it may kill as surely and less comfortably than would total neglect.

Rest is so important in maintaining the general strength that any treatment involving frequent serious disturbance of the patient ought to be looked upon with great suspicion. Disturbance of rest may do more than wear out the strength; it is just possible that it may increase the area of the local lesions. So little is known of the conditions favorable to the action of the diphtheria bacillus, and the following group of cases is so unusual, that they are reported for what they are worth.

Two internes, comfortably sick and occupying the same private room, amused themselves by playing ball for the greater part of an afternoon, tossing a folded handkerchief from bed to bed. On the following morning each of them was much prostrated, and each had an enormous increase of membrane. Two women, comfortably sick, acquaintances and also occuping a private room in common, were in and out of bed and in each other's beds many times in one evening, giving the nurse some trouble. The following morning each of them was much prostrated and with a great increase

[2] During these months there were 320 diphtherias in the service, including a few admitted with wrong diagnoses, but not including those in the wards on the first of February.

of membrane. Some twelve convalescent children were allowed to play together. They were so long in getting entirely well, that immediately after the occurrences just mentioned, they were all ordered to bed. They then began to recover one by one. These children had had scarlet fever as well as diphtheria.

Placing great stress on economizing strength, I think that care should be taken not to abuse the use of steam. It makes a depressing atmosphere, and if steam is concentrated about the bed by means of a tent, it also makes a close atmosphere, at times a very foul one. It is recognized that steam inhalation sometimes relieves dyspnea before surgical interference as well as after; and it is the abuse, not the use of steam that is objected to. I have no comment to make on its use after operation. Before operation, however, I think it should be intermitted long enough to find out if the occasion has passed, as we now know that the relief given by steam and poultices is occasionally permanent. Such permanent relief is so unusual that I was formerly inclined to think it occurred only in cases where dyspnea was due, not to membrane or infiltration, but to dryness of the mucous membrane caused by passing through cold streets. I have had, however, a few patients in whom this symptom has come on after days of residence in the hospital, and who have yet recovered under this treatment alone. Therefore, the rule, once dyspnea always operation, has a few exceptions. They are probably very few; and I should be sorry to write anything that would cause delay in seeking surgical aid for unrelieved dyspnea, even in case the immediate danger to life might not seem great. Such delay would mean wasted strength.

Among means of treatment, in which the present year's experience has taught me to place great reliance, is the combination of fresh air and sunlight. During February the wards were overcrowded, unavoidably so it seemed, and there was more septicemia than usual. For the first time in my life I learned to know the appearance of septic eruptions, although I had seen an abundance of septic diphtheria before. Among the children were many sore fingers, reddened about the nails. A few patients had red purpuric spots on the body as large as the thumb-nail. Others had an eruption closely resembling that of scarlet fever, but which in my opinion was not due to that disease. This eruption did not follow the regular march of scarlet fever from above downward, and the punctate spots were larger and quite purple. None of these patients lived long enough for desquamation. When, at last, enough admissions were refused to reduce the number of patients to the normal and the wards were cleansed, these eruptions suddenly ceased to appear. I recall one child desperately sick for weeks getting well, his improvement beginning on the day that he was moved from a small, crowded room to a bed in a large ward, where the morning sun streamed over him. The change for the better in each twenty-four hours was marked, and this was the only alteration in treatment. When the season was so far advanced that convalescents could be sent, and the beds of some who were not convalescents moved to the eastern piazza for the morning, and their dinners sent there, there was again sudden general improvement. Of course, this might take place in any disease, but the known destructive power of sunlight on diphtheria bacilli ought to be considered in connection with it.

It has been of interest to me to determine whether enlarged cervical glands and general infiltration of the neck were best treated by poultices or by ice-bags. After close observation of a large number of patients, I have no opinion as to which method causes these symptoms to disappear soonest; but a decided opinion that one or the other generally gives comfort, and that the large majority prefer the poultice, while a smaller number distinctly prefer the ice-bag.

Local applications to the throat are sometimes highly useful, although perhaps their importance is less than that of the general treatment. They are commonly made by gargles, swabbing or spraying. I have had little experience with gargles in diphtheria; swabbing is always objectionable to children. It frightens them and leads to a struggle, with corresponding waste of strength. If done gently it is sometimes preferred by adults, especially by those with very sore throats. Spraying seems the only practicable way of making these applications to children; but whether for children or adults, spraying should be done with the greatest gentleness. The mechanical irritation of a powerful spray is often extremely painful to an angry swollen throat, quite irrespective of its composition; and I believe that the complaints about the pain caused by certain sprays, depend more upon the manner in which they are used than upon anything else. There are times when any application, or even the opening of the mouth is painful, and there are adults who have decided preferences between the swab and the spray. I know of no reason for not consulting their preferences.

Peroxide of hydrogen has been used by me very largely as a local application. I think that it has been over-estimated but that it has a value; and I am sure that it is not the injurious drug that it has been said to be. For instance, it has been reported that solutions of fifty, fifteen, or even seven-and-a-half volumes are caustics. I think that these statements, as applied to the throat, must have originated in the use of a different peroxide from that which we have, or from a violent manner of use. It has not been my experience with the fifteen-volume solution furnished by the hospital or bought at various drug-stores in Boston. Children, as a rule, do not complain of it in spray, although they will not tolerate that or anything else applied with swabs. The same child will make no objection to the fifteen-volume spray in the mouth, will say that it does not hurt, and complain of the three-and-a-quarter volume in the nose. As a rule, adults say that even the fifty-volume spray does not hurt the mouth, although there are exceptions. Some even say that it is a relief to have the mouth cleaned with it. Complaints of the fifteen-volume spray are very rare. I have a few times seen a patch of denuded mucous membrane on the palate, due I thought to a fifty-volume spray. I have never seen this from the fifteen volume. I think that constant use of the fifty-volume spray is apt to redden the mucous membrane, although it is not sure to do so, and therefore that used in that strength it is probably an irritant. Being such, its continual use may possibly prolong the existence of the membrane. Whether I have or have not had this experience, I do not know. Some membranes last a long time with very little treatment, just as others disappear soon.

I have sprayed my own throat thoroughly with a fifteen-volume solution bought of an apothecary, and

it caused no pain although there was a slight sensation of effervescence. A fifty-volume solution procured at the hospital, and thoroughly pressed on absorbent cotton into the inside of the cheeks and lips until it began to be swallowed, caused very slight tingling, which lasted longer than the application. The same specimen rubbed into my wrist caused severe pain. Dropped upon the hand, it bleached it for thirty-six hours.

I repeated these experiments upon myself with another specimen, made by a private apothecary by boiling down the weaker solution of a different manufacturing chemist, and got identical results. The difference in the sensation in the mouth and on the hand was in each case most marked. Observe that the application to the hand and nose are painful, but, in the mouth the effect is much milder. Possibly a rapid dilution with saliva may account for the difference. It is to be observed that all my reports of the fifty-volume spray were when the application had been made by a trained nurse with great gentleness. I think we may conclude that the fifty-volume spray, while seldom a caustic, is too strong for routine use, if the object is merely to clean the mouth and not to exterminate the bacilli. Of its use for the latter purpose I will speak later. Second, any appreciable strength is too strong for the nose. It has the additional disadvantage that it probably penetrates the nose less far than most applications, because it fills the nostrils with foam, sufficiently to prevent the passage of a gentle spray. Third, there is no objection to the use of fifteen-volume solutions in the mouth.

So far, I have considered merely the question whether the peroxide of hydrogen does any harm. Does it do any good? It removes any bad odor from the parts it touches, and it cleans the dirty membrane, leaving a white instead of a gray or yellow surface. It does this almost immediately, and it probably does it by oxidizing and disintegrating the surface of the membrane. It appears to me that this is an advantage, that by removing a certain amount of *débris* we must remove a certain amount of the danger of sepsis, and this quite irrespective of whether bacilli are destroyed by the reagent or not. If, as is said to be the case, they are destroyed, so much the better. I say that the surface of the membrane is probably disintegrated, because I have known a large piece of membrane placed in a fifteen-volume solution immediately on being coughed up, to become completely disintegrated in about two and a half hours, and another in a fifty-volume solution in an hour. So long an exposure does not appear to me to be practicable in the throat, very often in one patient. If the treatment consists in a short application only, the gross appearances are the same, whether the fifteen- or fifty-volume solution is used.

When this drug was first introduced for diphtheria in the City Hospital, internes and nurses then on service in that department, and who had seen many different applications, became immediately enthusiastic, such of them as I talked with, over the new spray. I had myself been making use of corrosive sublimate (1 to 15,000), as I had formerly used salicylic acid and other washes, and it appeared to me that we had found something better. In 1892 I divided the service into four parts according to the location of beds, treating the throats in one with fifteen-volume peroxide of hydrogen, in another with corrosive sublimate (1 to 15,000), a third with Dobell's alkaline solution, and the fourth with a spray of boiled water. In a few days the throats treated with peroxide and those treated with corrosive were in general so much the cleaner, that the other two sprays were withdrawn. By cleaner, I do not mean, necessarily, that there was less membrane. It took longer to decide between peroxide and corrosive, but in a week the general difference in appearance between the two sets of throats, was such that I withdrew corrosive and made the use of peroxide general. It has the additional advantage of being purely local in its effect. I have twice known corrosive sublimate to salivate when used in weak spray. The nature of the diphtheria mouth is such, too, that mercurial poisoning is harder to detect than in syphilitic mouths, for instance.

I think, then, that where there is much membrane there is an advantage in disinfecting the mouth; that peroxide of hydrogen is practically such a disinfectant, perhaps technically so; and that it is one of the best, perhaps the best at our command; but that its uses should be confined to the mouth and what can be reached through the mouth. This is speaking of the weak solution.

It has been claimed that by prolonged applications of the strong solution, the membrane can be removed and the progress of the disease cut short. That the membrane can be removed is, I believe, true. That the progress of the disease can be cut short, is improbable, except in cases where all the bacilli are still on the surface. I have not observed that the use of this strong spray every two hours for a few minutes at a time, exerts any influence on the duration of the disease. Certainly, cases will continue for a long time, even when such treatment is begun immediately on admission to the hospital. Neither does this two-hourly treatment practically remove the bacilli in those cases in which it is continued after the disappearance of the membrane. They may continue to be found for weeks in spite of the treatment. I believe that I have seen a highly septic mouth become steadily less septic during three days because of the hourly use of the strong solution, it having been previously getting worse, but that this was at the expense of great prostration due to manipulation. I have not tried to repeat this observation on any other person.

The following history is worthy of being reported. An interne of the hospital who had seen, or at least heard of, persistent thorough use of strong solutions, entered my service as a patient. While perfectly polite, it was evident that he was anxious, and not satisfied that all was being done that might be. His case, too, was quite stationary. Therefore, I chose to begin for him the use of fifty-volume peroxide for a few minutes every hour, day and night. This began on the seventeenth day after admission. On the eighteenth he persuaded his nurse to give him half-hourly treatment, so that he was being sprayed fifteen minutes out of every thirty. On the nineteenth I forbade this extreme treatment, because he was frightfully prostrated. His pharynx was then half covered with membrane, but the next and every succeeding bacteriological examination were negative, although none had been so before. Local treatment was at once stopped and the membrane disappeared on the thirty-first day. Some critics would probably say that this man recovered through the heroic use of peroxide. Others that his

membrane continued long after he ceased to have diphtheria, as the result of local irritation. Possibly both might be right.

I have not felt warranted in repeating this experiment; nor should I have pushed things as far as I did with this patient but at his understood wish, he being entitled to an opinion and being in my care by regulation, not by choice. The case is, however, rather suggestive. It is barely possible that such treatment for a few applications at the very beginning of the disease is not to be condemned, provided the patient is strong enough and can be closely watched. If unsuccessful, however, just so much strength will be used up at the beginning of a prostrating disease.

Since becoming dissatisfied with the use of peroxide of hydrogen for the nose, I have gone back to insufflations of iodoform, first clearing the way if necessary with forceps or a spray of sterile water. This answers as well as any treatment of the diphtheritic nose with which I am acquainted, but leaves much to be desired in bad cases. In such cases, I doubt if any spray reaches the whole surface. The opinion of aurists seems to be opposed to a douche. Accidents have occurred which have led to loss of hearing and loss of life. Still I am not satisfied that in a few septic cases, the risk of driving diphtheria bacilli and other germs into the Eustachian tube may not be legitimate, in view of the gravity of the disease. The difficulty is in selecting the cases, because some very bad cases do recover without running this risk. I have no experience in this matter to report.

## REMOTE RESULTS OF THE REMOVAL OF THE UTERUS AND OVARIES.[1]

BY ERNEST W. CUSHING, M.D.

The question in regard to the removal of the uterus, which usually carries with it the appendages, is a very important one. It is a subject which it is well to consider because it is one of the latest developments of surgery, which promises a great deal and is overcoming the opposition to it. When, in 1887, A. Martin came over and performed the first vaginal hysterectomies for cancer, there was intense opposition. Reeves Jackson denounced the whole procedure in Washington, and the opponents said that it was a terrible and dangerous operation, and should not be tolerated for cancer even. Certainly that has passed now. When more operators began to do it, it was found that it was not dangerous. Martin did the first three cases in Boston, in September, 1887. In March, 1891, I reported before the Obstetrical Society of Boston, 21 cases with 19 recoveries; and I have done a very large number of vaginal hysterectomies since then for cancer, with even better average results. Anybody will now admit that the remote results of the removal of the uterus are good if it can save a woman from cancer, and about one-half the cases are saved for three or four years, and something less than that are saved permanently. I know it rather made me shiver when in 1885 Martin proclaimed that every uterus affected at all with cancer should be removed entirely—yet now this rule is established.

Then came the question of removal of the uterus for fibroids, and that again worked its way against opposition. Where the mortality used to be 60 per cent. it is now less than 20 per cent., and the best results give not over six to ten per cent.; so that the removal of the uterus for myoma is now as well established as the removal of the ovary for ovarian tumor. The increased safety of it and the advantage to suffering women is forcing surgeons continually to operate in cases where they would not have done it a few years ago; that is, the increasing knowledge of the bad effects of leaving myomas, such as complications which finally ensue from pressure on the ureters, on the intestine, from degeneration of one kind or another, long-continued hemorrhage, complications of salpingitis, etc., have wrought such a change of opinions, that surgeons are much more ready to remove the uterus now than a few years ago. And some are going so far as to say — which makes the conservatives rather hesitate — that they will remove a fibroid the size of the fist to guard against future growth and accidents. Now, however, by the development of surgery it is found that by vaginal hysterectomy a small fibroid can be removed with ease and with practically complete safety. If we can essentially without danger remove the little fibroids, presently there will not be any big fibroids, just as there ought not to be any big ovarian tumors in civilized communities. Here is a fibroid I removed the other day. There was a prolapse and fibroid. The fibroid could not be brought down whole; but by pulling it down and splitting it, the whole thing was easily removed. The woman is cured of the prolapse. She does not realize that anything has been done to her. The entire absence of shock after vaginal hysterectomy, is one of the marvels of surgery.

If it is safe enough for that, then comes the question of removal of the uterus for prolapse. You know the difficulties of the operation for prolapse and all the different things tried. Finally, A. Martin propounded removal of the uterus for prolapse. Now it is done by many, and laid down as a proper thing to do. If a woman has prolapse and is past child-bearing, slip the uterus out; it is the easiest thing in the world, and fasten the stumps of the broad ligaments to the angles of the wound in the vagina. Now, when we can remove the uterus by the vagina so readily, I cannot see the need of doing it from above as Polk in New York does.

What are the remote bad results of removal of the uterus and appendages? What has been charged against it is, in the first place, production of insanity; and, in the second place, the production of obesity; and, in the third place, loss of sexual desire, by which I suppose is meant sexual feeling. Now, in regard to the production of insanity, it is a fact that various gynecological operations are followed sometimes by insanity. I remember out of perhaps some 900 cases of all sorts of gynecological operations which I performed in the Murdock Hospital there were some three cases of insanity, all of which recovered. I had one case at the Charity Club Hospital, where after removal of a large fibroid the woman became violently insane in a few days, but she recovered. I have one case of a fibroid removed two years ago, where the lady, although apparently sane, confesses that she has occasionally suicidal tendencies. She wants to commit suicide, but knows it is wrong and does not do it. How far that is insanity, some of the alienist experts will tell.

[1] Read before the Obstetrical Section of the Suffolk District Medical Society, November 28, 1894.

I reported last year fifty abdominal hysterectomies for fibroids. Those included only the ones I did at the Charity Club Hospital and in private practice. During the last year at the Charity Club Hospital I did 11 abdominal and vaginal hysterectomies altogether, and outside about 20. Now, out of 150 abdominal and vaginal hysterectomies, the only permanent bad effect of any kind I know of is this lady who says she has suicidal tendencies. (I do not mean to consider here the recurrences of cancer.)

Now, in regard to the removal of the ovaries and tubes, we are getting on ground which is not quite so satisfactory as that for the removal of the uterus. The removal of the uterus is done for certain very definite indications. It is done for cancer or fibroids or prolapse, or by the extension which some operators are introducing now as a means when the tubes are badly diseased and the interior of the uterus inflamed with gonorrhea, etc., of getting rid of the whole trouble at once; therefore, you have certain definite diseases or states or troubles which are, as I might say, mechanical, at any rate not nervous. You can see and feel and demonstrate them, and the woman knows what she is cured of after she is operated on.

In regard to the removal of the tubes and ovaries, we get into a mixture of several different conditions. If a woman has tubes and ovaries diseased, full of pus, big as potatoes perhaps, and high temperature, chills, likely to die, it is one's duty to remove them. You let pus out anywhere else; and you must let it out there. What the remote effects are is of no consequence; you must get her out of immediate danger. If the woman has catarrhal salpingitis or the remains of old salpingitis which has bound the tubes and ovaries so that every month she is in agony; if she has had packing tried, the uterus pried up, pessaries used and she goes from one doctor to another, damning the last one all the time, it is time to do something; and even if she is not entirely cured, she is cured of the worst of it, and she gets over this agony every month.

Then comes the question how much she is cured. A certain portion of these women continue to suffer. It is partly owing to conditions which could not be helped at the time; the uterus was brought up, but possibly it does not stay up; there may be new adhesions to the bowels, to the abdominal wall. Some of us keep running across these cases. I have had a case where a woman could not control her urine at all for three or four years. I found that the previous operator had put on a ligature which had got one of the epiploic appendages in with the stump of the ovary, and was pulling and pulling and twisting; and the epiploic appendage and a bit of the base of the bladder and stump of the ovary were all together, with this ligature in the middle. Her sufferings were because something had not gone quite right. In another case you will find firm adhesions to the abdominal wall; somebody has not pulled down the omentum, or there has been an adhesion of the intestine to the abdominal wall, or it may be that there are adhesions of the stump to the intestine or the bladder. There are these different complications, and they require the thing to be done over again, and a great deal of that work is gradually being done. Sufferings are caused by the fact that there is still some trouble which may require another operation.

Another class of cases is where there are cirrhotic ovaries. The great trouble is dysmenorrhea. First, the woman has medical treatment, then gets a surgeon, gets dilated, curetted and packed with gauze, and does not get any better, and somebody has to sit up and give her chloroform and load her full of morphine every menstrual period; and finally she has to have an operation, and you find something of which very little is said in the books. The first stage seems to be an enlargement of the ovary; it becomes large and white; gradually the white tissue begins to shrivel, until the ovary keeps getting smaller and smaller and harder and harder until there is no chance to swell and open and let the ovum out, and the woman suffers tortures. After she has suffered that way for years her nervous system is broken down; that is the result of the long-continued injury to the nervous system by the disease. It must not be laid up against the operation.

There is another class of cases, however, which are the weak-backed sisters who do not have any anatomical disease that can be discovered. They have pains, aches, miseries; they may have studied too hard, may be neurasthenic by nature, and they are very apt to suffer from dysmenorrhea; and finally somebody comes along and removes the ovaries, and they do not get a bit better. It is just as if a woman had neuralgia in the teeth, and you pull the teeth and it goes back of the ear. These women are miserable and would be miserable, and nothing I know of will stop it. The surgeon gets to recognize them as a "holy terror." The distinction in my judgment is that the pain does not limit itself strictly to the menstrual period. With the cirrhotic ovary, as I have found it, the pain is strictly limited then and there to when the ovary tries to functionate; but the woman who has pain in the head, pain in the back, and pain all over, is not a good case for surgery. Some of those women were operated on years ago. It is especially these cases where there is little to go on except pain, which are the legitimate causes of reproach to surgery; and I do not think surgeons are now as ready to interfere with those cases.

Then come the cases where the ovaries are removed for dysmenorrhea where there is a real anatomical basis, such as inflammation of the ovary, suppuration of the ovary, inflammation of the tube, adhesions; those are removed for disease, not dysmenorrhea. The woman has a right to have them removed, and if she is not entirely cured it cannot be helped.

There is one other cause of suffering that many set down to disease of the ovary, and that is varicocele of the pampiniform plexus. It is liable to give rise to various sufferings, such as pain, pressure, nervous and mental symptoms, similar to those caused by spermatocele in the male.

There are cases where the ovaries are removed for other kinds of nervous symptoms; in the first place, for hystero-epilepsy, epilepsy coming on at the menstrual period and at no other time. I have not seen many of those cases. I have operated in two; one was cured and the other ameliorated, but not cured. I fight shy of that all I can.

The cases where the ovaries have been removed in case of insanity, with the effect in a certain proportion of cases of curing the insanity, have been, so far as I know, always cases of anatomically demonstrable tubal or ovarian disease. The woman after long-continued suffering finally breaks down, gives way in the intel-

lect and is put in an asylum, and is found to have an old pus-tube or retroverted uterus bound down which is the centre and starting-point of suffering and probably a long course of morphine, and not a very small number of those cases have been operated on and occasionally one has been cured. The cure is not on account of the removal of the ovaries, it is on account of the removal of an inflamed and irritating mass, and it is possible it might be something else than the ovary and the removal of it might have the same effect.

Then come the cases where the ovaries have been removed for nymphomania and masturbation approaching idiocy. I have had only one of those cases. The woman was becoming insane, a terrible sufferer from masturbation, utterly miserable, felt she had committed the unpardonable sin. Within two days from the operation she said she felt as if a weight had been rolled off her soul; she got well. It took her six months to recover her nervous health. She first did work for her sister and helped about the house, and then came to me and confided that a widower with four children wanted to marry her, and I advised the marriage, which has been very happy. That is the only case of that kind I have seen reason to operate on.

In regard to this whole subject there is at present a sort of reaction in surgery. It was started a year or two ago by a paper by Dr. Goodell in which he set forth the various woes and evils which might follow removal of the appendages. Dr. Polk at Washington, at the meeting of the Congress of American Physicians and Surgeons, took up something in the same strain. He called attention to the fact that removal of the appendages which brought about the change of life, caused not only the temporary symptoms, flushings and various miseries which women have to go through at some time any way, but it also brought about atrophy of the vagina and genitals in some cases, and a loss in some cases of sexual desire and feeling, which certainly is a serious matter.

My experience, however, has been very different from that of Dr. Goodell. I have taken pains to inquire, both personally and through the superintendent of my private hospital who is a lady physician. The women have talked frankly, and almost none of them have complained of or admitted that they felt any difference in their sexual desires or feelings. As a matter of fact, actual sexual desire is not a condition in which most women take pride or feel it is anything to be particularly cherished or desired. It is rather an uncomfortable state. The ability under proper circumstances to have as much sexual feeling as they previously had is not impaired in the vast majority of cases. On the contrary, in all these cases where there has been inflammatory trouble where the women have been made sick, where they have been nursing a tender ovary, the removal of the disease which had caused suffering and extinguished sexual desire and made sexual connection intolerable has been of very great relief. The removal of the uterus has no more effect than removal of the appendages. Many of the women are married women, and they tell me they are just as well off as they ever were. That some of them grow stout I also believe; but some women grow stout any way and being laid off active exercise and pretty well fed and urged not to do anything and having good care, it is a good starter to getting stout.

Therefore, to sum up, my experience has been that the removal of the uterus has no more evil effects than the removal of the appendages alone, and that the removal of the appendages alone has in itself under very rare circumstances caused a loss of sexual feeling, that is, of the capacity for sexual orgasm, which is to a certain extent regretable, but those instances are very rare. If we take one hundred women whose ovaries have been removed I very much doubt whether you would get a much greater proportion who gradually lose their interest in sexual matters than in an equal number without the removal of the ovaries.

## ULTIMATE RESULTS OF THE REMOVAL OF OVARIES AND TUBES.[1]

BY J. G. MUMFORD, M.D., BOSTON.

The operation of removal of the ovaries and tubes seems to be gradually finding its proper place in surgery, as the indications for it, the manner and extent of the proceeding, the subsequent treatment and the results obtained are better understood.

We have no more right to talk about these operations as distinct species, and to discuss the results as a whole, than we have to talk in a general way about the uniform results of skull fractures or leg amputations. Twenty-five years ago most severe compound leg fractures were amputated. Six or eight years ago very many painful ovaries were removed. In both cases we have got beyond that stage of cutting off the offending member. It is now for good cause only, and as a last resort, that the uterine appendages are removed. Any tyro — I had almost said — can tie off a Fallopian tube; it is the ingenious and successful surgeon who restores the organs to their normal function.

The personal factor of the patient enters largely into this question of ultimate result. The patient very commonly wishes the operation for the relief of subjective symptoms. Often when these symptoms are but partially relieved she expresses the greatest satisfaction. On the other hand, there are cases in which the operation is imperative — for gangrenous, sloughing or suppurating organs, and in which their removal has saved life. Yet we often find the patient constantly thereafter complaining of recurrence of the old symptoms and not at all grateful that her life has been saved. It is obvious, therefore, that the question of ultimate results is in one sense a relative one and must be answered by each individual surgeon and patient. On the other hand, one may look at the question from the broadest point of view and ask if the general health of woman has not been improved by this operation.

I found that I could put my hand on seventeen cases of removal of tubes and ovaries, of which some sort of a subsequent history could be given. Two were cases of cystic ovaries; painful, about the size of pullet's eggs. In one I did the partial operation of Polk and Pozzi on both ovaries. The woman has since married and had a child. She menstruates regularly and is free from pain. From the other woman both tubes and ovaries were removed. Ever since the operation she has, on sitting, pain, sometimes very severe, which seems to be referred to the right stump. She looks upon herself as a castrated woman

[1] Read before the Obstetrical Section of the Suffolk District Medical Society, November 28, 1894.

subject to pain equal to what she had before the operation, and that seems to me to be the case. Of eight cases of pyo-salpinx, one has much pain, one has a hernia, two much recurring headache and four may be considered well. There were seven cases of what are commonly called chronic salpingitis and ovaritis. Of these, three are well, three much improved and one not improved. All but two of these cases are taken from hospital records or from the lists of other men whom I assisted.

In all these cases in which the symptoms have recurred the variety of the symptoms varied, and they are by no means always the same as those originally complained of. The commonest complaint seems to be pain. How frequently neuroma of the stump occurs I do not know. I saw it once at the hospital in the case of a secondary operation. I think in the service of Dr. Richardson. The patient had had an ovarian tumor removed two years previously, and on opening the abdomen to remove a cyst on the other side a neuroma was discovered in the old stump. I fancy that this may be a more frequent cause of post-operative pain than is generally supposed. It is common enough in the stump after arm and leg amputations. Pain is frequently referred to contractions from adhesions. That this may be a most serious complication after abdominal section I had proof from a case of appendicitis in which I assisted Dr. Richardson. The patient appeared nearly well, some six weeks after the operation, when quite suddenly pain and symptoms of total obstruction of the bowel appeared. The abdomen was opened a second time and a coil of intestine, nearly strangulated by a recent band of adhesions, was liberated. This seems to be an unavoidable complication. It is said that the free use of some aseptic oil in handling the viscera will obviate it, but that remains to be proved. However that may be, it seems most probable that that old bugbear — adhesions — is at the bottom of very many of the ultimate bad symptoms after abdominal section. Of course, the skill of the operator and the perfection of his technique enter largely into the question.

I feel confident also that we are inclined to send our patients home too early, and to get them out of bed too soon. It cannot be that the reparative processes which demand the old surgical safeguards of rest and immobilization can be completed in two or three weeks. Our wound is out of sight and our knowledge of its condition must be gleaned from symptoms, yet I suspect that could we look inside the abdomen at the end of a month we should find the healing still incomplete in many cases.

It is unwise, too, to lose sight of our patients so soon after the operation as is the usual custom. The general health must be most carefully restored and the condition of the bowels, bladder, kidneys and stomach regulated. We have all of us seen a severe attack of post-operative constipation the apparent exciting cause of recurrent pelvic abscess.

I have not considered especially in these remarks the results of the removal of large tumors of the ovary and broad ligaments. For these the operation is usually imperative, as it is generally for pus tubes, and in both these cases the results must be considered good even if there remain some subsequent pain and other bad symptoms. Indeed, it is rather in the operation of choice that the patient most often asks herself, Was it worth while?

In looking over the recent literature of this subject I find that most of the writers dwell on the disasters of a few specific cases or take the subject as a whole without dividing it into its special classes.

The general feeling of such men as Lusk, Sutton, Mundé, Coe, Goodell, Remote, Kelly and others is that, as a whole, these operations are very distinctly valuable in proper hands.

Kelly's article in the *Johns Hopkins Bulletin* for 1890 is the most satisfactory summary that I could find. His results from ninety-six cases are very similar to those which I have given.

### CONCLUSIONS.

(1) Cases for operation should be carefully chosen.

(2) The patient's general health previous to operation should be more carefully looked to.

(3) She should be kept longer in the hospital or under treatment.

(4) The imperative cases, as a rule, show a better subsequent history than the elective.

(5) The cure is more often relative than positive.

## Medical Progress.

## RECENT PROGRESS IN ORTHOPEDIC SURGERY.

BY E. H. BRADFORD, M.D., AND E. G. BRACKETT, M.D.

(Concluded from No. 6, p. 135.)

### INWARD ROTATION OF THE TIBIA.

TILANUS [20] describes a method of treatment of this deformity by what he terms rotation-straps (elastic straps connected above with a leather belt fastened around the waist, winding spirally around the thigh and leg and connected with the outer side of the shoe. When these straps are tightened, the feet are turned outwards and the inversion of the foot is thereby corrected.

### CONGENITAL ABSENCE OF THE TIBIA.

Joachimsthal [21] reports a case of this deformity which was treated by transplanting the head of the fibula from the outer side to the middle of the end of the femur, correcting by means of tenotomy and fasciotomy the varus position of the foot. The foot and leg and knee were fixed in a plaster bandage, and the foot placed upon a high sole to equalize the difference in length. The child was allowed to walk about, and was able to do so. The writer collects a number of cases of the same deformity, and the article is of value for reference as well as for being illustrative of the successful management of a case of an unusual deformity.

### OPERATIVE INTERFERENCE IN CONGENITAL DEFECTS OF THE ARM OR LEG.

Rincheval [22] describes the operative interference in this hitherto incurable deformity. The deformity consists in the absence of the radius or one of the long bones of the leg, and consequent malposition of the hand or foot. The operation consists of splitting by means of the chisel the end of the ulna and inserting the carpus (modified in shape if necessary by means of a chisel) in the split portion of the end of

[20] Zeitschrift für orthopädische Chirurgie, Bd. 3, H. 2, 1894, p. 136.
[21] Loc. cit., Bd. 3, H.2.
[22] Archiv. für klinische Chirurgie, 1894, B. 48, p. 802.

the ulna or the tibia in such a way that the inserted wedge is held by the two splintered fragments. The operation has been done by Bardeleben and also by Bardenheuer, and would appear to have been thoroughly successful. In one instance the ulna which was much curved was successfully rectified by fracture.

### ABSENCE OF THE DIAPHYSIS OF THE THIGH.

Grisson,[23] reports a case, with illustration of this unusual deformity. He mentions in the literature of the subject a case reported by Billroth. He mentions also other cases reported by Dumas, Buhl, Breschet, Veil and Duméril. Anatomical measurements are given.

### ANCHYLOSIS OF THE JAW: OPERATIVE INTERFERENCE.

Helferich,[24] reports a new method to prevent the subsequent relapse after the ordinary operation of excision in anchylosis of the lower jaw. The method consists of the insertion of a reflection of a muscular flap from the temporal muscle between the resected portions of jaw and the articulation.

### ARTHRODESIS IN INFANTILE PARALYSIS.

Karasiewicz[25] reports 61 cases treated by arthrodesis (87 operations); 33 were of the knee, all with satisfactory results; 44 of the ankle, with excellent results in 23, satisfactory results in 19; failure in two; two of the hip; three of the shoulder, with good results in two; satisfactory in one.

Broca[26] describes the method he employs in the ankle. It consists of an open division of the tendo-Achilles, and a long external curved incision which separates all the outer ligaments. The astragalus is then thrown outwards and the cartilage curetted, and that on the lower end of the tibia as well; the scapho-astragaloid articulation is also curetted. A plaster-of-Paris bandage is applied, and worn six weeks. He mentions eight cases.

### RELAXATION OF THE JOINTS AT THE LOWER EXTREMITIES.

Leser[27] describes a condition of the joints which is accompanied by pain, a sense of weariness, uncertainty in standing and walking, heaviness of the limbs and an unusual lateral mobility at the knees. The anatomical conditions are not to be easily defined. There seems to be a thickening of the capsules and a loss of elasticity. The cause of this may be an injury of the joints followed by an effusion into the joint which stretches it, or too prolonged traction upon the joint may cause it. As to the treatment, he prescribes massage, aspiration of the fluid if effusion is present, and if traction be necessary the protection of the knee by plaster-of-Paris. After treatment by proper apparatus, the protection of the weak joints from strain is of benefit.

### ARTHROPATHIES FROM SYRINGO-MYELIA.

Perrey[28] reports two cases of diseases of the joints following syringo-myelia. This affection, which results from a disturbance in the central canal of the spinal cord, leads in certain cases to diseases of the joints. They are chiefly of the upper extremity which is the reverse of what is the arthropathies from tabes. Men are more frequently afflicted than women. There is sometimes development of vesicles in the skin of the neighborhood. The inflammation of the joint is either a hydarthrosis or a suppurative synovitis. These may either be acute, appearing suddenly, or chronic. There is slight pain, heaviness of the limb. There is in the joint, sometimes subluxation and finally a distortion. The diagnosis from rheumatoid arthritis is to be made, but the latter is never as acute and never has the dislocation which follows this form of arthropathies. The disease is sometimes mistaken for leprosy. The only treatment is immobilization with orthopedic apparatus, puncture, arthrotomy.

### TREATMENT OF STIFF JOINTS BY MEANS OF MECHANICAL PASSIVE MOTIONS.

Krukenberg[29] has for some time successfully carried out the treatment of stiff joints by means of a variety of apparatus which is carefully described in his article. The principle is that of the pendulum, the force being graduated according to the length of the pendulum as regulated by a sliding weight. The appliances are ingenious, but can only be understood by an examination of his illustrated article.

### THE ELASTICITY OF THE CAPSULE OF JOINTS.

Fessler[30] has made a number of experiments in regard to this point, and has come to the conclusion that the capsule is less easily torn than the bone is broken. The capsule tears in different joints at the tension of different weights: the shoulder at 146 kilos; the hip, 380; knee, 350; foot, 248; toe, 62 and 30; fingers, 83 and 79; hand, 184; elbows, 169.

### HALLUX VALGUS.[31]

The conclusions which these writers form are as follows: that the resection of the head of the meta carpus does not interfere with the activity of the joint if the sesamoid bones are retained. Well-marked cases must be treated by resection. Wedge-shaped osteotomy of the neck of the metatarsus is especially indicated if the sesamoid bones are dislocated and deformed and cannot act as a support. Tenotomy is sometimes an additional assistance.

### PLANTAR FASCIA.

Ledderhouse[32] reports what he considers a tear of the plantar fascia. The condition consists of thickening and a local swelling of portions of the plantar fascia. This he considers to be scarred tissue, as a result of previous partial tears. In certain cases he thinks that excision is necessary, but in some instances a properly constructed shoe will be sufficient.

### ON THE ELASTICITY OF THE HUMAN FOOT.

Goledíwski[33] has made a very careful study of the elasticity of the human foot. He has proved by means of tracings and casts that the foot increases in length and width both actively and passively. The active increase in size is through the ordinary action of the muscles. The passive increase is developed by

[33] Zeitschrift für orthopädische Chirurgie, 1894, p. 243.

he weight of the body. The stretching of the foot is also accompanied by an alteration in the form. The foot is wider when standing than when hanging and wider still on sitting. A sudden increase of weight can have a traumatic effect, tearing of the fascia on the inner side of the foot.

CONGENITAL DISLOCATION.

Hoffa[34] reports the results in the later cases of his operation; he finds that the acetabulum in the majority of cases was either well developed or partially so but never absent. In looking up the literature, Hoffa found the acetabulum in 104 out of 111 cases; in only seven was it absent or not marked. In order to secure the head of the femur in the acetabulum, Hoffa considers deepening of the acetabulum always necessary, even if the head is easily put back; and he prefers to deepen the acetabulum more rather than less. He prefers not to operate on children over ten. In a case three years after operation, he found that motion at the joints was excellent; the lordosis had disappeared, and the waddling gait had almost entirely gone. Two children with single luxation, one operated on at five and one at a year and a half, showed three years and one year after the operation, a perfect result. The joint was perfectly firm and without any limitation of motion. The failure of attempts to correct deformity without operation Hoffa considered as due to the presence of the ligamentum teres. In the cases he had seen, it was as a long broad band, and it is impossible for the head of the femur to build a proper new joint while the ligamentum teres lies between the pelvis and the head of the femur.

Bilhaut[35] reports a successful case in a child of ten. Kirmisson,[36] reports a death from the operation in a child of twelve, and disagrees with Hoffa in the belief that the acetabulum in these cases comes in the thickest part of the os innominatum. It seems to him that it comes in the thinnest portion. If an attempt is made to deepen the acetabulum, there is danger of perforation, which, however, is not necessarily a great surgical disaster.

Angeres[37] and Koch[38] report successful cases of Hoffa's operation. Phocus[39] reports cases of attempted reduction by the Paci method (namely, the Bigelow manipulation method), and is doubtful of permanent benefit in congenital cases through this mode of treatment.

PATHOLOGICAL ANATOMY OF CONGENITAL DISLOCATION.

Lorenz[40] describes the anatomical conditions of the joint. The acetabulum is always rudimentary. In certain cases in older children it is entirely covered with a thick mass of fibrous tissue. In a majority of cases the acetabulum is shallow, but can be found by the finger. In very young children the hollow is three cornered. He claims that the pelvis at the point of the acetabulum is thicker than is supposed. The upper end of the femur is atrophied, and the head is more or less flattened. The neck is shortened. The ligamentum teres is originally of normal condition, but after the fifth year Lorenz has found the absence of the ligamentum teres the rule. It is rather broader than normal, and usually double as long. The capsule forms the cap over the luxated head.

CONGENITAL DISLOCATION.

Mikulicz[41] reports five cases treated by the mechanical correction by means of a traction apparatus. The apparatus itself is extremely clumsy, and the cases as reported indicate a result similar to what has hitherto been obtained by this method, namely, a marked improvement, after two or three years of treatment.

THE EFFECT OF CONGENITAL DISLOCATION UPON THE SHAPE OF THE PELVIS.

Muhlenbrock[42] after investigating the alterations in the shape of the pelvis, which are to be seen in congenital dislocation from the malposition of the head of the femur and the lordosis, concludes that the pelvic deformities which result are of no significance in child-bearing. He has reported two cases of this deformity where the birth took place without any difficulty.

SEPTIC OSTITIS IN CHILDHOOD.

Mr. Edmund Owen[43] considers the acute inflammation of the diaphyses with relation to the early diagnosis, and its differentiation from acute articular rheumatism with which it is not uncommonly confounded. It usually begins with a chill, followed by fever and local inflammation, swelling and pain, and if allowed to continue, becomes an extensive osteo-myelitis. There is usually a spot of elevation with an area of redness, but this differs from acute articular rheumatism in that the heat, swelling, pain and tenderness are close to the articular area but do not involve it, at least not at the first. The tenderness is limited to the region of the [illegible] and connective below the junction of the cartilage, and then these structures point there is a definite thickening outwards at that point which sometimes misleads in the direction. The diagnosis is that two parts may be simultaneously affected. Usually by the time that the cases are seen by the surgeon the disease has become more or less extensive, and in the operation a sequestrum is usually found, but the early and radical operations give favorable results.

DISLOCATION FOLLOWING ACUTE ARTHRITIS OF INFANTS.

Dr. A. Thorndike[44] in an article which considers the bacteriological side of this subject, reports a case which shows that the dislocation from this cause is difficult to reduce in proportion to the disorganization and destruction of the joint. He operated five months after the subsidence of all acute symptoms, and reduced the dislocation by the operative method employed by Hoffa for the correction of congenital dislocation of the hip. A large, finger-like exostosis had grown from the lower border of the femoral neck, and projected so that the head could not be brought into the acetabulum. Its removal presented no difficulty. The case is instructive because it shows that even long-standing dislocations from acute arthritis may be reduced, and that bony obstacles to reduction may be successfully overcome by the Hoffa operation should it be impossible to accomplish it in the ordinary way.

### THE RESULTS OF CONSERVATIVE TREATMENT OF TUBERCULOUS COXITIS.

Prof. B. Bruns[45] gives in this article a rather unusually valuable series of statistics, as they are compiled from a large series of cases which extended over a long period of time (in all forty years), and are followed out for a long period dating from the discharge of the patient as cured. The article deals mainly with the results of conservative treatment, and is of special value, not being confined to the consideration of any one method of conservative treatment, as during this long time there has been necessarily fundamental changes in the therapy of coxitis, varying from the crude methods of blistering, hot irons, etc., to the more modern methods of fixation or traction, and also the more radical surgical measures. The investigators were aided in their search of cases by the fact that the population about Würtemburg is quite fixed; and in this way the records of 600 cases were collected, and of these it was found possible to examine 200. Among the things of interest which were found in this investigation was the number of cases which were considered at first as coxitis, which were of a different nature. One of these was the condition described by Mueller under the name of *Schenkelhalsverbiegung*, of which this clinic at Tübingen shows more than thirty cases. Another is the condition of acute osteo-myelitis beginning at the diaphysis, the hip-joint being peculiar in this respect as this point is within the capsular cavity. Fifty cases were found in this class, which pursued either a sub-acute or a chronic course; but these were ruled out from those under investigation, and also those the duration of which was less than one year and a half, and also all such cases in which there was not sufficient information. In this way the number was reduced to 390, of which 321 were treated conservatively and 69 by resection. He gives the following conclusions:

(1) Tuberculous coxitis occurs almost exclusively during the first two decades of life: 48 per cent. occur in the first decade, 37 in the second, and but six in the third.

(2) In one-third of the cases of tuberculous coxitis the disease pursues its entire course with no manifest formation of pus. In two-thirds an abscess develops, with rupture and fistula formation.

(3) Fifty-five per cent. of all cases of tubercular coxitis treated conservatively are cured. The time required for the cure averages four years.

(4) Death resulted in 40 per cent. of the cases; in the majority from the development of tuberculosis in other organs, particularly the lungs and meninges, or to a general miliary tuberculosis. In the fungo-purulent form death was usually due to amyloid degeneration, progressive suppuration and septic infection. Death ensued after an average duration of three years.

(5) In individual cases the ultimate result is markedly influenced by the occurrence or non-occurrence of suppuration; in the non-purulent forms 77 per cent. were cured, in the fungo-purulent only 42 per cent. The occurrence of suppuration within the joint more than doubled the mortality (75 to 52 per cent.).

(6) Of great importance in the prognosis is the age of the patient at the beginning of the sickness. As a rule, the prognosis became worse with the increase of age; the first decade gave 65 per cent. of cures, the second 56, the third and fourth only 28, and the fifth and sixth none. In the fungo-purulent form there were practically no cures when the patients were more than twenty years old.

(7) Of those persons who were really cured of tubercular coxitis, many suffered subsequently from tuberculosis of other organs. Of these, six per cent. died of phthisis during the first decade, nine per cent. during the second decade, and seven per cent. during the third and fourth decades.

The results, considering the cured cases, are gratifying, and are about midway between widely differing figures of many other observers; which is probably accounted for by the fact that the investigation extended over so long a period, and included so many cases, which reduced to a smaller degree the error of accidental variation. In considering these cured cases, the usefulness of the limb was noted. It was found that a majority were able to earn their living, although the gait was in most cases limping, the leg atrophied to a greater or lesser degree, and there was almost always found more or less shortening, and contraction and immobility of the joint. The deformity was found to be usually that of flexion, combined either with abduction, as was found in two-thirds, or with adduction as in one-third of the cases. The contraction is compensated by a tilting of the pelvis, but in some cases where the flexion was as great as forty-five degrees and the apparent shortening marked, the locomotion was difficult. This shortening appears to be largely from an arrest of the growth in the femur, and is always present when the disease occurs in childhood, undoubtedly due in a great measure to the disuse, as the tibia and the foot are also found to be short. The most marked cases of shortening were found to follow those cases of acute osteo-myelitis, in which there is more likely to be an injury to the epiphyseal cartilage. The other form of shortening is due to the high position of the trochanter on the pelvis, which is found in about four-fifths of the cases. The average amount of shortening from this was four centimetres. This condition is due to destructive changes in the acetabulum, and is found to be much more frequent than from dislocation of the head of the femur. In this result the typical position of the leg does not differ greatly from that in dislocation, but the chance of retaining a useful leg is much greater.

### COXA VARA.[46]

Hofmeister, Kocher, Whitman, Kirmisson, all report cases of an affection which was at first thoroughly described by Mueller in 1888, although it had been previously referred to as a lack of firmness of the bone. Rotzer, Scrubel, Launstein and Hoffa have also reported cases. The affection comes either in early youth or about the time of puberty. There is a general weak habit, a limp and waddling gait. The trochanter stands above the Nelaton line. The feet are ordinarily turned out, but in exceptional cases they are turned in. The cases are mistaken for hip-disease, for congenital dislocation, and for fracture of the neck or separation of the epiphysis; also for hysterical coxalgia. Rest in bed, with traction, is recommended in the milder cases during the acute stage; in later stages in children, either apparatus to turn the feet in or out, or osteotomy.

### THE TREATMENT OF TUBERCULAR ABSCESSES BY THE INJECTION OF IODOFORM.

Dr. Kirmisson[47] favors the treatment of many of the abscesses from tubercular bone lesions by this method, and cites cases in which the cure has been accomplished after several injections, varying from two to four or five. He prefers the solution of iodoform and ether to that of glycerine and naphtol. The difficulty of the treatment as practised has been to thoroughly evacuate an abscess cavity filled with caseous pus, which clogs the canula, on account of which it has been found necessary to dilute the contents of the sac, and this has been followed even in spite of great precautions by less favorable results. In the present method this objection is avoided, in that no attempt is made to previously wash out the cavity. Another objection to the other method is the uncertainty of the amount of iodoform which is left in the abscess cavity, and the occurrence in a number of instances by iodoform intoxication. In the method advocated a definite amount of iodoform is used, which is regulated to the age of the patient and the size of the abscess, usually from five to fifteen grammes of a ten-per-cent. solution of iodoform and ether. It is rarely found that one injection is sufficient; and if the fluid is reproduced without a distention of the sac, a fresh injection after four weeks is practised. As a rule, after a few injections the quality of the fluid may be tested, and the prognosis in that way be determined, and the treatment regulated accordingly. If the fluid is found to be true pus, it is necessary to repeat the injections. If, however, the fluid is found to be lighter in consistency, and colored only by the iodoform, it may be considered that the abscess is undergoing resolution, and a fresh injection is not necessary; but it may be inferred that the resorbtion is progressing, and that the cure will be complete.

### INTRA-CELLULAR IGNIPUNCTURE IN THE TREATMENT OF TUBERCULAR ARTHRITIS.

Dr. Kirmisson[48] in this article has described a method of treatment which at one time was attempted, but on account of the unfortunate results has never been received with favor, as in most cases the point of puncture became infected, and the arthritis became acute, which in many cases ended either in amputation or in the loss of life. Since the days of aseptic surgery this danger is avoided, and the author reports several cases in which the method has been employed with favorable results. In the treatment of these the skin is thoroughly cleansed in the same manner as would be the case if an ordinary operation was to be performed, and the fine point of the cautery, heated to a red point, is inserted along the point of the greatest development of the granulations. From twelve to eighteen punctures are made, and the diseased portion is in this way thoroughly reached. The part is then filled with iodoform gauze, the limb encased in plaster, and a certain amount of compression used. He reports several cases in which the results were very satisfactory. At the time of writing there were a number of cases where the puncture was used, and the recovery was rapid considering the ordinary length of time of these cases of arthritis which are not opened. It is recommended on account of its easy accomplishment and being within the reach of most practitioners.

### HISTOLOGICAL CONSIDERATIONS OF OSTEOPLASTY.

Dr. Barth[49] gives the results of further investigations based on sixty-five experiments of operations upon animals. The results of these experiments confirm the opinion that detached fragments of bone do not become vitalized when transplanted, but are replaced by new bone-formations. Ollier's differentiations between autoplasty, homoplasty and heteroplasty are not of importance, as the method of healing is always the same without reference as to whether the transplanted bone is from the same species of animal or not. This becomes devitalized, and a new bone-formation takes its place, the method of substitution being the same without reference to the materials. The foreign substance becomes penetrated and enveloped by a new vascular growth coming from the periosteum and marrow, by which process it becomes in a way rarefied. In this tissue is then deposited a new bone-formation, and by a continuance over some months, the foreign substance becomes entirely replaced by living bone.

The process is not uniformly distributed, as in the long bones for instance the new bone-formation begins in the marrow, meeting some difficulties toward the periphery, but after the process of substitution is complete, the margin of this defect cannot be discovered even microscopically. In the skull, however, the margin of this new bone can be discovered macroscopically by a flattening. The retention of the periosteum over the surface seems to have but little effect, except in such instances of osteoplastic skull resection after the Wolff-Wagner method, in which a larger part of the bone retained its vitality, and only in the cut border is found the necrotic substance. The material which seems most difficult to revitalize is decalcified bone, it being absorbed so quickly that the ordinary scar tissue results. The sponge, however, seems to fill the condition best. Barth reports a number of cases in which the bony defect was filled with a sponge, the skin sutured over the surface and the result desired was obtained.

### EXCISION OF THE SAC IN SPINA-BIFIDA.

M. Robson[50] considers the operative treatment of spina-bifida. From his experience with these cases, he divides them into three classes; the first, in which operations should not be attempted; the second, in which it cannot be considered as necessary; and the third, in which it should be attempted.

He considers that the operation should not be tried when the tumor is large, and there exists a large longitudinal opening into the spinal column, or when there is existing paraplegia, or when there is not sufficient skin to recover the meninges. Also, it is not indicated when the pouch is small, and the skin over the tumor is too thin to protect the tumor. It should, however, be performed when the tumor communicates with the canal through a small opening, or when there is sufficient healthy skin to cover the orifice. When, however, the skin is thin over the most prominent part of the tumor, the operation must be considered as one of considerable difficulty; also, when filaments of nerves are involved in the tumor. It is better to avoid cutting the meninges, but rather to return them to the canal after puncture.

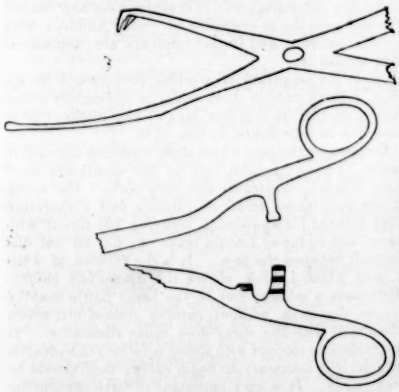
### INDUSTRIAL SCHOOL FOR CRIPPLES.[51]

Denmark and the adjoining Scandinavian countries Sweden and Finland have shown the world the need of a new charity. The blind, the deaf, the feeble-minded have for a long time enjoyed the privilege of founded institutions of instruction, but it has remained for the Scandinavians to first develop industrial schools for congenital cripples. The originator of the first industrial school for cripples was a clergyman by the name of Knudsen, of Copenhagen, who opened his school in October, 1872.



After the International Medical Congress at Copenhagen, an impulse was given to this form of charity, and similar schools were started in Gothenburg, Karlskrona, Helsinborg and Stockholm, in Sweden; Helsingfors, in Finland; Christiania, in Norway. In Christiania a school was started in 1872 by Miss Fischer. An organization has been formed to support and educate and make self-supporting all cripples in the community and surrounding country. That the number of these is not small is shown by the fact that in Finland alone the census showed the existence of 8,000 helpless cripples.

## New Instruments.

### ORTHMAN'S INSTRUMENT IN VAGINAL FIXATION OF THE UTERUS.

BY FRANK M. SHERMAN, M.D., HAVERHILL, MASS.

A DESCRIPTION of the instrument of Orthman, here figured, and the operation of vaginal fixation of the uterus by its use, may interest those of your readers who are not familiar with it. A recent writer in the New York *Medical Record* has given an excellent description of the indications for, and a good method

for the performance of the operation. The use of this instrument, however, greatly facilitates the procedure. The instrument consists of two parts: A sound, which is put into the uterus, and the hooked portion which hinges with it and seizes the outside of the uterine neck. It fastens to the "sound" portion like an ordinary artery clamp.

The operation known as Mackenrodt's vaginal fixation as performed by Martin in Berlin is as follows: the sound is introduced, the companion portion hinged and hooked into the outside of the cervix; then by carrying the handles backward, the uterus is anteverted, and held in that position. The whole uterus is now pulled downward as well as backward, putting the anterior vaginal wall on the stretch, and a vertical incision is made from one or two centimetres below the meatus urinarius down to that portion of the forceps that is hooked into the uterine neck. The vaginal mucous membrane is dissected back on each side; the bladder is now peeled off from its connection with the uterus, its connection to the cervix uteri and vaginal vault cut on each side, and it is then pushed up to the upper angle of the wound with the fingers. A catgut ligature is now passed through the edges of the vaginal incision, at its upper angle, including also the muscular wall of the bladder, and tied. The anterior surfaces of the corpus and cervix uteri now fill the incision, and are fastened with three or more strong silk ligatures, after which the vaginal incision is closed with catgut, with or without an anterior colporrhaphy, as may be indicated. Martin often combines this operation with his well-known anterior and posterior colporrhaphy and perineorrhaphy.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

JOHN T. BOWEN, M.D., SECRETARY.

REGULAR Meeting, Monday, November 26, 1894, DR. C. F. FOLSOM in the chair.

DR. A. L. MASON read a paper on

MEDICAL TREATMENT IN DIPHTHERIA.[1]

DR. F. M. BUCKINGHAM also presented a paper on

DIPHTHERIA.[2]

DR. GEO. B. SHATTUCK: I have had, in common with Dr. Mason, a pretty large and long-continued hospital experience in reference to diphtheria, and I regret that my time came before we were in sight of anything that looked like a promised land; we were wandering in a wilderness. We had the disadvantage of great difficulties in the diagnosis. It is only lately that we have the knowledge of the Klebs-Löffler bacillus and provision for making cultures and examination of cultures which enables us to differentiate the different classes of sore throats. We had to decide by gross appearances whether a given case was one of tonsillitis or one of diphtheria, and of course we were often mistaken. Our position in reference to treatment was equally unsatisfactory. I can remember very well through many years every year some method of internal medication was suggested or some method of local application was proposed which was going to be almost a specific, and every one of them was a disappointment. I tried a great many of them, and I finally settled down to the general method of support-

[1] See page 145 of the Journal.
[2] See page 147 of the Journal.

ing the strength of the patient by nourishment given in the way best suited to the individual case, by stimulants, by tonics, and in addition to that by keeping the throat as clean as it could be kept without irritating the mucous membrane or exhausting the patient; and it seemed to me, and I still think, that that was the *summum bonum* we could reach under the conditions which then offered themselves to us. With reference to the local treatment, I have used the weaker solutions of peroxide in my later services. I never have used the stronger ones, the fifty-volume solution, so that in reference to it I cannot give any testimony. So much for my experience as far as past history is concerned.

The present situation depends upon the value which further experience gives to the antitoxin treatment. If the triple claims made for it as (1) a prophylactic, (2) a curative, (3) a bactericidal agent, are justified, then the future of diphtheria and our relation to it will be greatly modified. The ease and comfort of treatment will be increased, mortality rates and period of isolation will be greatly diminished. Less hospital accommodation will be required for equal number of cases and for better results.

Having spoken of the past and present, permit me to say one word about the future. If the serum treatment is to become general then comes the very important question and by no means an easy one, what arrangements are to be made for providing the community under a sufficient and proper guaranty with the material for this treatment. It is the business of boards of health to prevent disease. It is not considered generally to be their business directly to provide remedies. Of course, this matter may be regarded from the prophylactic point of view as well as from the point of view of treatment. There is no doubt that in a commercial community like ours, if a thing recommends itself, the commercial spirit will provide for it. But even wanting this, there should be, as we know perfectly well from the difficulties which we have had with reference to vaccine virus — and this would be a still more difficult question — some guaranty and some inspection for such products if they are furnished to the community by private commercial houses, and we should probably have to look to State and local boards of health for such guaranty. This question is a perfectly legitimate one for our consideration.

DR. F. H. WILLIAMS: I have been very much interested in the papers and the discussion; and, if you will allow me, I will try to add a word on a little different side from those which have already been taken up. The treatment of diphtheria may fairly be divided into the local and the general treatment. It is to be recognized, I think, that local treatment is not practicable in very young children; neither is it practicable for laryngeal cases, except so far as you may call the use of steam or calomel fumigation local treatment. I think when the disease is as far down as the lungs or larynx, that it is inaccessible, or when a patient has been sick many days that you cannot expect to do as much by local treatment as in the early days of the disease.

As regards the use of local treatment in the nose, it is very important to bear in mind that much milder treatment must be used there than in the throat. The nose will not tolerate strong solutions; for instance, of hydrogen dioxide, a one- or two-volume, sometimes a five-volume solution is as strong as I am ever willing to use.

As a rule, that is in most of the cases of diphtheria, the disease begins in the throat at points which are accessible to local treatment.

A great variety of remedies have been used locally, and most of those have been mentioned this evening — corrosive sublimate, chlorinated soda, ten-volume solution of hydrogen dioxide, or a weak salt solution or boiled water. It is of the first importance in using local treatment to be sure of the strength of what you use. For example, take chlorinated-soda solution. A year or two ago I wrote ten prescriptions for the official solution of chlorinated soda, which were sent to ten different apothecaries. The solutions were analyzed afterwards; and I found that out of the ten only two were up to the mark, and one or two were something like one-tenth, and one of them one-twentieth, as strong as it should have been, and three of them were not chlorinated soda at all. No matter what is used, it is very important to know the strength of what you are using.

As regards the strong solutions of hydrogen dioxide, at first I used a twenty-five-volume solution. It was then known as the fifty-volume solution, now as the twenty-five, since the last edition of the Pharmacopœia, January 1, 1894. The results seemed to me encouraging, and I have come to the conclusion that the twenty-five-volume solution is frequently a serviceable local application; but in many cases a fifty-volume solution is required for a time. In my opinion the strength of the solution of peroxide of hydrogen to be used depends entirely upon the conditions which present themselves. Sometimes a twenty-five-volume solution is quite useless, and it requires a fifty-volume solution to be of any real service.

As regards the use of these solutions, it is extremely important that they should be used gently and always with the co-operation of the patient. Never use force under any circumstances; it is astonishing how readily you can gain the co-operation of young children with a little patience, and if the solutions are applied as they should be.

As to the frequency with which they should be applied, I think once in three hours is sufficiently often, that is, during the first few days of the disease; after that once in four hours, or less often.

Concerning the pain which these solutions are said to cause. I have a patient now in the diphtheria ward who, I think, illustrates this very well. He spoke of the pain these solutions caused; and I therefore tried without his knowledge spraying his throat with water, and so far as I could make out he did not distinguish between the two. It is the friction of what is used which I think causes the discomfort chiefly. Oftentimes a solution out of the same bottle may be put on the swab without causing discomfort, which when used with the spray does cause discomfort. If one wishes to succeed with strong solutions of hydrogen dioxide, it is necessary to begin early; they should be used gently. It is very important to have efficient instruments; if the instruments are inefficient, the solutions might in many cases better be in China so far as any service they are likely to do the patient is concerned. Solutions should be of known strength and have a sufficient amount of hydrochloric acid. The hydrochloric acid in the hydrogen-dioxide solution is the active agent, so far as germicidal action goes,

rather than the hydrogen dioxide itself. They are both serviceable; the hydrochloric acid should be in small percentage, one-fifth of one per cent. — about as much as there is in the gastric juice.

It is important to know how to apply the solutions, and also important to know when to stop their use. How not to use the solutions of hydrogen dioxide, I think is illustrated very well by some cases which were reported in the *Medical Record* a few weeks ago, cases treated at the Willard Parker Hospital in New York. A solution of hydrogen dioxide in ether, known as pyrozone, was used to make the hydrogen dioxide solutions. The manufacturers, I think, claim that these solutions are nearly neutral; in other words, the important germicidal element is left out, the special property of the hydrogen dioxide itself being the disintegrating power. Another thing which I thought was very unfortunate was the great air-pressure which was used in the atomizer. The air was pumped up to a pressure of eighty pounds, and then allowed to run down to thirty pounds; and when it got down to that point it was again pumped up to eighty pounds. I should as soon think of pumping a whirlwind into a patient's throat as using an atomizer with a pressure of something like thirty to eighty pounds. The pressure of the air should be about six pounds or at most eight pounds. You want just pressure enough to throw whatever you wish to apply so that it will reach the desired part.

Another instance of the way in which one should not use the hydrogen-dioxide solution may be illustrated by the remark of some one in a medical meeting when the acid was spoken of. He said it was easy enough to get rid of the acid by adding bicarbonate of soda, that is, diminish its value as a germicide and decompose the hydrogen dioxide. I know of no applications at all efficient, so harmless as are suitable solutions of strong hydrogen dioxide. It seems to me that they tend to reduce the congestion, and under their use the glandular swelling is more rapidly diminished; they have these good effects beside reducing the amount of membrane and cleansing the throat.

As regards the redness in the throat, the reddest and most prolonged case of congestion of the mucous membrane I have seen, fairly to be called a raw-beef throat, was one where salt solution was used for a number of weeks, and the bacilli also persisted for a long time in that throat.

I think it is important to bear in mind that after the strong hydrogen-dioxide solutions have been used for a few days that cultures should be made, to see whether or not the bacilli of diphtheria are present. As soon as they are absent I think all local treatment may be stopped, as a rule. And, as a rule, in the cases I have followed the bacilli have disappeared before the membrane. There are three or four cases now in the diphtheria ward at the hospital in which bacilli have not been found for some days, although the membrane still remains in the throat.

It is very difficult to compare cases in one institution with those in another, and those in one city with those in another city. For example, the mortality from diphtheria in New York seems to be decidedly less than in Boston.

As regards the length of time during which the bacilli remain in the throat after the use of such treatment as corrosive sublimate, chlorinated soda, ten-volume solution of hydrogen dioxide or one-half per cent. salt solution, I can offer a few figures in 34 cases. In this series of cases the bacilli were still present on the average on the twenty-seventh day of the disease, and absent on the average on the thirty-sixth day of the disease. In another series of cases, 26 in number, where the strong hydrogen-dioxide solutions were used (and these were more severe cases than the others), on the average the bacilli were present on the twelfth day of the disease, and absent on the average on the eighteenth day of the disease, saving, you see, quite a considerable number of days in the cases where the strong dioxide solutions were used.

The mortality is always a very difficult thing, I think, to estimate. Of 18 cases treated within the first three days, the diagnoses of which were not based on cultures, only one patient died, and that was a laryngeal case at entrance. Of 30 cases of diphtheria, the diagnoses of which were based on cultures, two died; one had been vaccinated a few days before and did not seem to be in good condition, and the solution used was found to be much below the purported strength; and one was a child four years old, who took the treatment perfectly well one day, became delirious on the second day, so that treatment was impracticable, and died on the following day.

Local treatment has been recommended and used by Löffler. He presented some cases at the Congress at Budapest in which he used a solution composed of alcohol (64), toluol (36), and creoline or metacresol (1 to 2). As this solution produced a strong burning sensation in children he added to it 10 per cent. of menthol. He reported 96 cases, three-fourths of which were cases of diphtheria; none of these cases died.

As regards general treatment, antitoxin seems to be the thing most promising now as an internal remedy. My experience with it is quite small. I have used it in four cases in which a preventive dose only was used, and in five cases in which a larger dose was used. It seems to me a good way to treat diphtheria would be to inject the antitoxin early and in sufficient quantity, and then use carefully the strong solutions of hydrogen dioxide locally, being very careful to give good food — I think that is of the utmost importance.

Most of the cases, I think, require only a small amount of brandy. I think it is important not to use alkalies, such as the solutions containing lime-water or Dobell's solution (bicarbonate of soda) locally. The alkaline solutions seem to do very little good, and probably they do harm. As regards other internal remedies, various ones have been recommended. Corrosive sublimate does not seem to me to have any good, but rather a harmful effect. Strychnia, in cases of paralysis, or iron in cases of anemia, is serviceable.

Dr. C. F. Withington: The interest in this discussion is increased in my own case from the fact that I take my time of duty in the contagious wards very soon; and I confess I do it every year with great misgiving, from the apparent failure of all treatment in these cases. The other day I looked over the results of the last service which I had, in the summer of 1893, and while the figures are of no special value, I will give them briefly, as they are figures showing the relative frequency of the cases as they presented themselves then.

Contagious Service at City Hospital, in July, August and September, 1893.

Of diphtheria and pseudo-diphtheria there were 116 cases, of scarlet fever 57, and of mixed cases 19; total 192.

Of diphtheria and pseudo-diphtheria, 79 cases were examined bac-

teriologically, the Klebs-Löffler bacillus being found in 59, or about 75 per cent.

This ratio would give, out of 116 cases, 75 per cent. as true diphtheria, or 87 cases, the deaths being 10, or 46 per cent.

Of these, 17 deaths followed intubation, 5 tracheotomy, and 2 intubation and tracheotomy.

Thus, the deaths in operative cases were 24, and in medical cases 16, or 25 per cent.

Scarlet fever deaths 12, or 21 per cent.; in mixed cases 6, or 33 per cent.

From hospital report, one year, to January 31, 1893, the mortality of diphtheria (clinical not bacteriological diagnosis) was 49 per cent., of mixed cases 47 per cent., of scarlet fever 8 per cent.

Bacteriological examinations were not made in all cases, for one reason, among others, that many of the patients entered moribund. Hence it is probable that of the unexamined cases a larger proportion were diphtheria than of those examined. This would increase the total cases of true diphtheria about 87 and would make the actual mortality per cent. lower than 46 per cent. It is generally supposed that the use of the bacteriological method of diagnosis gives a higher mortality of the cases, by diminishing the total number of cases of diphtheria, through the elimination of cases of pseudo-diphtheria. But, on the other hand, it is also true that with the extension of bacteriological examination to mild cases we are getting to recognize as true diphtheria cases not so considered previously. Cases are now admitted simply on the strength of finding the Klebs-Löffler bacillus when the patients are not at all seriously sick. A very high mortality existed among the mixed cases. That mortality was higher than that of diphtheria alone and very much higher than that of scarlet fever. We have cases which come to the hospital with diphtheria and afterwards develop scarlet fever. This is an unfortunate state of things, but one which does exist. During the three months there were eight cases in which patients entered with diphtheria, and from three to thirteen days after entrance scarlet fever developed.

It seems that there is quite a variation from year to year in the percentage of the complications. For example, last year there was almost no post-diphtheritic paralysis; on the other hand, the percentage of nephritis was extremely high. There were twelve cases of albumin without casts (seven in diphtheria and five in scarlet fever cases); but of albumin, with casts (epithelial and granular in character) and the clinical picture of nephritis, 33 in diphtheritic cases, three in scarlet fever and four in mixed cases. Four of these died with nephritis, the cause of death being sepsis. An endocarditis was the complication in eight cases, pericarditis in two cases, chorea in one case, acute miliary tuberculosis in one case. Abscesses of the glands which required opening were present in two cases of diphtheria and five of scarlet fever.

Of the specific things which have been vaunted for diphtheria, even within my memory, there are so many that it is disheartening to go over them. Of course, we all use local treatment for the membrane of diphtheria; and everybody admits, I suppose, that local treatment has its value, for the membrane is to be looked upon as a manufactory of the toxine which is the great source of danger. It seems to me, however, there are two or three things about the nature of the case which suggest a marked limitation to the value of local treatment. In the first place, the amount of membrane is no gauge of the severity of the infection. The two things do not go hand in hand. It is not always the cases of greatest amount of membrane that show the greatest amount of systemic poisoning. In the second place, it is well known that the Klebs-Löffler bacillus does not exist on the surface of the membrane, but is shielded in the trabeculæ of fibrin which constitute the membrane, and nothing applied externally can reach any large number of those bacilli. Third, there is the dangerous exhaustion of a child if he fights hard against local treatment; and, finally, there is the very great importance of avoiding any trauma of the throat. The producing of a wound of the throat is almost certain to furnish a new nidus for the growth of the bacillus and to influence the progress of the disease for the worse. I remember the case of a man last summer who came in having had diphtheria on the 5th of July, being supposed to have recovered from the diphtheria, having gone about his work and preserving the bacillus of diphtheria for a long time afterwards. He had been about his work for two months, and it was found at the end of two months that the Klebs-Löffler bacillus was present. On looking into his throat it was seen that he had had perforation of the soft palate near the uvula, and a small foramen existed, and under that foramen was situated a little bit of grayish membrane which had undoubtedly lain there all the time and been the source of infection. It seemed impossible to get at that membrane to make application or expose it to the influences of the air. It was undoubtedly the fact that the bacilli had been preserved there so long because of the peculiar anatomical relation of things; therefore after considerable hesitation I simply snipped the small band of tissue which closed in the foramen in order to expose this place. Instantly, after this man's two months of health, the membrane spread over the cut portions of the tissue; and, although he suffered no ill effects from it, the sudden leaping into activity of the disease was very manifest indeed. It seemed to me a proper thing to do because the thing had gone on two months, and might have gone on indefinitely. It stopped and the Klebs-Löffler bacillus disappeared after about a week of residence in the hospital; but the great importance of avoiding any trauma was emphasized by that case.

There is one method of local treatment that is free from some of the objections which attach to the swab and to the more violent treatments, and that is the method by irrigation. In the first place, a little patient can be treated by irrigation without being raised up, treated lying on the pillow. The end of a tube can be inserted into the mouth between the cheek and the jaw, and a current of warm fluid, either sterilized water or a solution of boric acid can be allowed to run in and out on the lower side of the mouth. It covers the membrane fairly well; and has the advantage of not being able to produce any violence, not stirring up the patient, washing away a certain amount, if not of the Klebs-Löffler bacillus at least of the other organisms which so often complicate the disease and add to the gravity, and possibly washing away a certain amount of the toxine which may have formed on the site of the membrane.

The contest in the body between the disease and the conservating forces in diphtheria, I suppose, is carried on mostly by the serum. We used to be taught that the micro-organism of diphtheria never went outside the membrane. I believe the bacteriologists tell us now that it sometimes does. But for the most part it maintains its place in the membrane and the damage it does is done by the absorption of toxines into the blood; and it is undoubtedly true that it is not

phagocytosis as much as the effect of the serum of the blood which finally gets the better of the disease. That is one thing which gives considerable promise to the antitoxin treatment. And one of the advantages which appear at once is that unlike so many other treatments it certainly is free of any possibility of harm. There is no record of any injurious effect other than occasional urticaria following the use of the serum injections, and it seems difficult to suppose any injurious effects can result.

Dr. W. H. Prescott: A remark made in my hearing by the late Dr. Doe when I was sick with diphtheria in 1885 under his care, seemed to contain all that was best regarding the local treatment of diphtheria. It was not meant for me to hear, but it was this: He had ordered an application of iron and glycerine, equal parts, and said to the house-officer, "If it irritates his throat do not use it, as it is of much more importance not to cause any irritation than to make the applications to the membrane." At that time I had had no experience with diphtheria; but since then all the experience I have had has gone to to prove the truth of the statement then made, that anything which causes an increase of irritation or pain in the local application is wrong in theory, because the pain causes a diminution of the strength, and the irritation causes the membrane to extend more rapidly after the application than before it. Of the many treatments of diphtheria which have come up each has had its run, and then either something new or the do-nothing policy has taken its place. There are only a few methods that need be spoken of. My experience at the hospital leads me to think that the internal administration of corrosive sublimate or of turpentine and the local use of peroxide of hydrogen are all attended with serious disadvantages. The treatment by sublimation of calomel merits a further trial. The last treatment that I would speak of is the treatment with the continued irrigation with solution of soda or some other bland solution — I think the substance or the solution used is not of so much importance as that it should be mild and non-irritating. This seems to be the best local treatment that has been given to us as yet. About the treatment of post-diphtheritic paralysis of which Dr. Mason has spoken, I perhaps may be allowed to say a word, as I suffered from it myself, and found strychnia, which I took on the advice of the late Dr. Hooper, to immediately benefit the paralysis of the palate, but to have no effect on the other paralyses.

Dr. J. L. Morse: I merely wish to emphasize the importance of not doing any harm in the local treatment of diphtheria. I should class peroxide of hydrogen with the actual cautery, nitric acid, etc., it being less dangerous only as it is less powerful. I should say the only safe local treatment is irrigation of the throat and nose with some unirritating solution. It makes no difference what it is. I also want to call attention to calomel fumigations in laryngeal obstruction. It seems to me I have seen very good results with them; far better than any obtained with steam. As to the persistence of membrane with peroxide, I am certain I have seen the membrane kept up by peroxide.

Dr. Shattuck: Dr. Buckingham's reference to the beneficial effects of sunshine, I think, is an important point. There is a private room at the end of the diphtheria ward at the City Hospital exposed to the south-west where the sun comes in nearly all day long, and I have noticed that all the patients I have had in that room — simple coincidence it probably is not — have done extremely well.

Dr. Mason: It is quite evident that there is a very general unanimity about the measures of treatment in diphtheria which relate to the preservation of strength, and not doing anything harmful to the patient. As to local measures there is an equal amount of disagreement; and I think this in itself shows that it is very fortunate that the time has come when we may be no longer obliged to decide whether we shall use this wash or that, having a means of treatment at hand which will obviate the necessity of so much disturbing of the patient. That, indeed, seems to be a great advantage of the antitoxin method. I noticed that Dr. Buckingham thought feeding by the nasal tube a cruel method, and that his results were unfortunate. That has not been my experience in the few cases in which I have used it, probably in older children. I do not remember ever using the tube in a child under four or five years of age; and I have never found, after two or three times, that they objected to it. It is a choice between using this method and allowing the child to starve if the deglutition paralysis is complete. One child was nourished a month in this manner, and got completely well. It may be a choice of evils, but it certainly is not painful and not cruel, if the child is old enough to understand what is being done. It is necessary in but few cases, of course.

Dr. G. H. M. Rowe: The city of Boston has expended nearly half a million dollars on its hospital for infectious diseases. Other cities in Massachusetts have also added to their general hospital buildings, isolating wards for the treatment of infectious diseases, particularly diphtheria. In the line of the very valuable suggestion made by Dr. Shattuck, it seems to me to be the duty of the medical profession of this city to see that some active measures are taken by the city so that we may have our own antitoxin. Ought not the State to devote at least two per cent. of a sum of money that the city of Boston alone has devoted to a hospital for infectious diseases? It may be premature to propose definite action at this meeting, but I would suggest to the members present that they seriously consider the idea given by Dr. Shattuck, and that it be acted upon at as early a date as practicable. I believe the Board of Health of the city of Boston have decided to devote a limited amount of money to this purpose. It would seem more fitting for the State Board of Health to take action in the matter. I suggest that it be ascertained whether during the early part of the session of the legislature active steps could not be taken to procure an appropriation for this purpose.

## SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR OBSTETRICS AND DISEASES OF WOMEN.

JAMES M. JACKSON, M.D., SECRETARY.

Regular Meeting, Wednesday, November 28, 1894, Dr. G. H. Washburn presiding.

Dr. E. W. Cushing spoke on the

ULTIMATE RESULTS OF THE REMOVAL OF THE UTERUS AND OVARIES.[1]

[1] See page 151 of the Journal.

DR. J. G. MUMFORD read remarks on the

ULTIMATE RESULTS IN THE REMOVAL OF OVARIES AND TUBES.[2]

DR. J. J. PUTNAM: There is only one part of the subject on which I feel qualified to speak, and I do not know that I can throw light upon that. As Dr. Cushing said, there are two classes of cases which one can separate in a general way; those where the ovaries are diseased and where the operation is undertaken for direct or indirect result of the disease, and those where the ovaries are as far as we know healthy. I think it may be said, however, that so far as I know it is a rather difficult matter to determine whether the ovaries are healthy or not. Some years ago I collected and reported a number of cases which had been operated on by Boston surgeons, most of them by Dr. Johnson. I was very much struck with the fact that in many of these cases, although there had been no manifest signs of disease before the operation, the microscopical examination showed that the ovaries were not really healthy. The practical question which presents itself to us most strongly is this, whether the removal of the ovaries is ever a suitable treatment for the clear cases of one of these functional nervous diseases — hysteria, neurasthenia, hystero epilepsy, pelvic neuralgia or insanity. Now I think, to begin with, it is but fair to state what it seems to me is the neurological opinion of the present day on that subject; and I think that would be decidedly against operation. Dr. Mitchell and Dr. Goodell have stated in unqualified terms that they think it practically never justifiable. At a meeting in Washington, Dr. Lusk and Dr. Sinclair of Philadelphia, with Dr. Mitchell, put themselves quite strongly for this position. Dr. Edes reported a number of cases in this last year which gave an unfavorable showing for this operation. There were several deaths, and on the whole the good results were very few. I hold in my hand what, so far as I know, is the latest monograph on the subject, a paper published this year by a physician of Berlin, which takes the position that operation is not a suitable treatment for these diseases, and that the adoption of it is based on an incorrect conception of the nature of the trouble for which it has been used. I cannot but think that there is something to be said on the other side. In the first place, among these cases which I collected there were a good many excellent results. Dr. Richardson speaks of the fact, which we all know to our regret is largely true, that the neurasthenic patients are hard to treat by any such method, and often hard to treat any way. With them the results are not brilliant. Nevertheless, I know a patient who could be called neurasthenic, who suffered from pain in the back of the head, sleeplessness, general distress — a nervous patient; and she obtained extreme relief from the removal of the ovaries, which turned out to be somewhat enlarged and excessively hard. The operation was done by Dr. Elliot. She was not one of the worst types of neurasthenics, however. It seems to me we ought to take into consideration the fact that we do occasionally get very great improvement, and occasionally cures, which if they do not establish an operation on a satisfactory basis are, nevertheless, worth something. The operation is a matter of last resort, or I suppose should be; and if from a lot of insane persons one occasionally gets relief in this way, that is something.

Among the class of cases for which the operation has been done I think we should make distinctions. They are not all equally susceptible of cure, and the severest are least susceptible of cure. More can be accomplished in the relief of vague pains and lesser degrees of nervous disorder than in the relief of well-marked hystero-epilepsy — for example, if of hereditary basis or of insanity or real epilepsy; and yet occasionally true epilepsy seems to be relieved in that way.

The question arises as to the nature or the theory of the operation. If it does good, how does it do good? Is the result a matter of coincidence, or is there any rational basis? In regard to that point it seems to me we are still a good deal at sea. This monograph of which I speak deals with that matter. The writer points out that hysteria is now conceived of as a mental disease, and if that be cured, it is by mental means. This is my own view. He reports a number of cases in which diseases were not cured, but made worse. It seems to me, however, that although these diseases are mental and to be dealt with by mental means, that sometimes an operation becomes a mental means. If a patient's mind has been concentrated on it, looks forward to such operation, that may furnish just the suggestion which is needed to bring about the cure; and it seems to me if we can set aside cases where the ovaries are really the source of local irritation, that is the way the operation is to be regarded. It is not so much the bringing on of premature menopause as it is the inducing of a new state of mind which is more favorable to recovery. We should not deceive ourselves about the matter. Many patients complain, not only about the ovarian pain, but of general pain. Charcot tried to set aside a special form of hysteria which he called ovarian hysteria. Now I think it is acknowledged, no matter how well localized ovarian pain and distress may be, whether it radiates down the thigh in a manner to suggest the crural nerves, nevertheless it is quite capable of being purely a symptom of hysteria or of neurasthenia, just as pain and tenderness in the back may be entirely apart from any local condition; and, therefore, I think, it is important that this fact should be recognized, that if we remove the ovaries, we do so for pain which has its source in the mind. If there is anything to be gained by the operation — and it seems to me occasionally there is — it seems to me that while it is due occasionally to the removal of ovaries which are really more diseased than we can tell from the outside, partly perhaps by the induction of premature menopause, yet it is mainly due to the establishing of a more favorable mental condition. We must ask whether there are not other means to be used; and of late I think a careful study of mental therapeutics, the light thrown on it by hypnotism and suggestion, has enlarged our power of dealing with these patients in this way, and we ought to use such means before we resort to those of surgery.

PATHOLOGICAL SPECIMEN.

DR. CUSHING: Here is a uterus which I removed on Friday from a woman who had had twelve children and had a prolapse. The uterus is badly torn on one side. I was not going to remove it. I was going to do an anterior and posterior colporrhaphy and cu-

[2] See page 153 of the Journal.

rette it. I used the dilator with the slightest pressure, and felt something give a little. I passed the sound, and felt it went far up. Not knowing whether it was going into the broad ligament or thinking it might have gone into the peritoneal cavity I concluded to remove the uterus. That made a short, light operation. If I had not done that what should I have had to do, even if there had been no accident?

In the first place, that cervix would have had to be very carefully repaired; secondly, anterior and posterior colporrhaphy and repair of the perineum would have given an operation four times as long. I show it as a caution, how little effort in certain cases may break through an old thin cicatrix — just a little push, and I had sundered something.

## MASSACHUSETTS MEDICAL SOCIETY.

### COUNCILLORS' MEETING.

A STATED meeting was held at the Medical Library, Boston, on Wednesday, February 7, 1895.

The meeting was called to order at eleven A. M. by the President, Dr. FRANK K. PADDOCK. Ninety-three Councillors were present.

#### APPOINTMENT OF DELEGATES AND COMMITTEES.

On nomination by the Chair, the following delegates to other State medical societies were appointed:

*Maine:* Drs. R. T. Edes, Jamaica Plain; J. F. A. Adams, Pittsfield.

*New Hampshire:* Drs. O. Warren, West Newbury; W. S. Everett, Hyde Park.

*Rhode Island:* Drs. J. R. Bronson, Attleboro; A. M. Pierce, New Bedford.

*Connecticut:* Drs. T. M. Breck, Springfield; A Wood, Worcester.

*New Jersey:* Drs. T. H. Gage, Worcester; C. P. Hooker, Springfield.

Committees were appointed:

*To Audit the Treasurer's Accounts:* Drs. A. D. Sinclair, Walter Ela.

To fill vacancy in Committee of Arrangements, caused by resignation of Dr. Henry Jackson, Dr. Paul Thorndike.

The Committee on Medical Diplomas, through its Chairman, Dr. Forster, presented the following report:

"Your Committee on Medical Diplomas has carefully considered the alleged delinquencies of the College of Physicians and Surgeons of Boston, as set forth in the letter of Dr. William A. White and referred to your Committee for investigation and report, and beg leave to submit the following:

"That your Committee has given a hearing to the Faculty of the College of Physicians and Surgeons, and from the facts there presented and from evidence derived from other sources, recommends that the Councillors of the Massachusetts Medical Society withdraw from the College of Physicians and Surgeons of Boston the recognition voted said College at the meeting of the Councillors held June 9, 1891."

After a prolonged discussion the report of the Committee was adopted, with but four dissenting votes.

The Committee appointed at the last meeting to consider the proposed amendment to By-Law XVII, making the ratio of Councillors one in twelve, instead of one in eight, of the membership of the District Societies, reported through Dr. White as follows:

"The present proportion of Councillors, one to eight, was fixed when the Society was much smaller. It has become a large, unwieldy assembly, numbering 226, and is rapidly increasing. It is altogether too large for a deliberative, executive body, much larger than is appointed for similar functions by corporations, as directors, trustees, legislators and the like.

"If the amendment be adopted, the Council would still consist of 150 members; and even the smallest districts, composed of such small numbers as 21, 28 and 32 respectively, and which have at present three Councillors, would still have two representatives each. Suffolk has 58, an absurdly large representation.

"In the opinion of your Committee, the duties of the council would be more easily and fitly performed if its numbers were reduced to the proposed ratio."

In accordance with the recommendation of the Committee, amended by Dr. Harvey, it was voted that By-Law XVII be amended that it shall read:

"XVII. Councillors shall be chosen by the District Societies, as directed in By-Law XIII, each Society choosing from among the Fellows residing within its district in the proportion of one Councillor to every twelve Fellows, or a majority fraction thereof."

This amendment will come before the Society for concurrence.

## Recent Literature.

*Notes on Military Hygiene, for Officers of the Line.* A Syllabus of Lectures at the United States Infantry and Cavalry School. By ALFRED A. WOODHULL, Major Medical Department, Brevet Lieutenant-Colonel United States Army. Pp. 150. New York: John Wiley & Sons. 1890.

This is a conveniently bound book, and presents the pith of lectures on military hygiene delivered to the class of 1889 at the Infantry and Cavalry School. It undoubtedly will be of value to officers in general. It takes up the following subjects: Selection of Soldiers, Military Clothing, Food, Habitations, Camps and Marches, Sewers and Waste, Water, and Preventable Diseases.

We are glad to see a book of this kind appear which is addressed to line officers, who, as a rule, are lamentably ignorant in reference to matters of military hygiene. It is not sufficient that a commanding officer should recognize that his surgeon should be a man of ability, and that his advice should always be carefully considered. To-day it is necessary that he himself should know not alone the principles of the art of war, but he should be thoroughly familiar with the principles of hygiene. Paragraph 153 shows what the importance of this subject may be to a successful general:

"The German army in the war of 1870–71 is the only one known to have kept its mortality from disease below that from battle. This probably depended upon the shortness of the war, the rapid succession of battles, the trained troops, and presumably upon its exact discipline being exerted for the care of the men as well as in other directions."

This book, conveniently arranged in sections, if placed in the hands of officers will do much towards supplying accurate knowledge. It is a book which would be well adapted for officers of the National Guard and Volunteer Militia.

THE BOSTON

# Medical and Surgical Journal.

THURSDAY, FEBRUARY 14, 1895.

## RADICAL OPERATION FOR INFILTRATING CEREBRAL GROWTHS.

RADICAL operation by excision of infiltrating tumors of the brain (gliomata, glio-sarcomata, sarcomata) has in general been looked upon with disfavor by surgeons, owing to the supposed danger of cutting into cerebral tissue. The teaching of localization has impressed the idea more and more that injury to the motor cortex must lead to permanent paralysis, and that therefore excision of cortex or underlying white matter should be scrupulously avoided. As a consequence of this perhaps partially justified timidity, operations are constantly being done with entirely negative results, so far as permanent relief to the patient goes. The skull is trephined, the dura opened, and the brain exposed, the tumor in a large proportion of cases being found. If the new growth be not definitely marked off from normal brain tissue, in other words if it be of the frequent infiltrating gliomatous type, the dura is replaced, the skin flap sewed, and the patient, often with increasing hernia cerebri, left to die, with relief of pressure symptoms, but with no outlook for prolonged life. Such is the usual routine.

In view of this fact, and the entirely negative result of most of our cerebral surgery, it is a satisfaction to draw attention to two cases recently reported of bolder methods, with results which justified the boldness. One of these is reported by Dr. Alfred C. Wood of Philadelphia, and the other by Dr. Chas. E. Beevor and Mr. Chas. A. Ballance of London.

Dr. Wood's case,[1] in brief, is as follows: Patient, a man, aged twenty-eight, noticed in August, 1892, occasional twitchings of left hand; later, epileptiform attacks, paresis of left arm, occasional attacks of vomiting, headache, double optic neuritis; later, face and leg of same side somewhat affected.

*Diagnosis.*— Probable tumor of right cerebral hemisphere, involving primarily arm centre, progressive in character.

*Operation.*— One and one-half inch trephine opening. Dura purple, tense and bulging, not adherent. Dura opened. Convolutions congested; much bulging. Incision showed what seemed to be a cyst surrounded by altered brain substance, later shown to be a new growth with central softening. Tumor infiltrating in character; no line of demarcation nor evidence of encapsulation. Tumor removed piecemeal by means of knife, scissors and curette. Operation discontinued only when healthy brain tissue appeared to have been reached. Cavity left about the size of a large walnut. Patient made good recovery from ether, with complete left hemiplegia. Sensation not impaired. Rapid improvement in motion of leg. Complete recovery of facial paralysis; some improvement in use of arms.

*Pathological Diagnosis.*— Glioma.

Return of growth soon after first operation. During the interval no headache, no spasms. Vision normal.

*Second Operation* about four months after the date of the first, in May, 1894. Demarcation of tumor and pathological tissue more definite than at first operation. Diseased tissue thoroughly removed. Wound closed without drainage. Immediate effects somewhat more serious than after first operation, but good recovery.

Five months after leaving the hospital the patient walked well without cane. The left leg was somewhat spastic. Arm not much improved. Has had no treatment by massage or electricity. Scalp over seat of operation depressed. No evidence of return of growth. The patient, apart from his physical disability, is perfectly well.

It is easy to forecast the result in this case had the conservative policy been adopted and the tumor regarded as inoperable, which, according to preconceived ideas it was. Instead of rapidly increasing symptoms and inevitable death, the patient, at last report, was a healthy, though partially-paralyzed man. If the growth recurs, as of course, is likely, the wisdom of the operative procedure is in no way invalidated.

The second case[2] of Beevor and Ballance is equally suggestive.

*Clinical History.*—Patient a woman, age thirty-nine, married. Gradual onset of paralysis, involving, in order, right ankle, knee, hip, and extending after lapse of seven months to joints of the right hand, and then to the whole of the upper extremity. Finally, affection of speech; this accompanied by headache, vomiting and optic neuritis. Gradual deterioration of mental condition. Some blunting of sensation on the right side. Face escaped. No family nor personal history of importance.

*Diagnosis.*— Sub-cortical cerebral tumor, not involving the internal capsule.

*Operations.*— July 11 and 17, 1894, being performed in two stages. At first operation, skull opened and dura exposed. Considerable bulging of dura. At second operation, dura opened over as large a space as possible. Cortex bulging especially over upper part of ascending parietal convolution of left side. Cortex mottled, thinned and easily broken through, exposing tumor. New growth found to be continuous with and infiltrating the cerebral substance. Consistence of tumor softer than normal brain substance. Free incision made through cortex over an area of about two and one-quarter inches in diameter, and the included part (brain and tumor) removed by means of a silver spoon. The writers say: "The tumor extended to the medial surface of the hemisphere, and so a part of the marginal convolution and quadrate lobe was removed, the falx being clearly exposed. In this way as much of the tumor as was visible was removed, but as the line of junction of healthy and diseased tissue was so indeterminate, it is not possible to say that the whole tumor was excised; it is, indeed, probable that it was not. At the close of the operation the brain presented a large cup-shaped cavity, nearly two inches deep and the size of half an orange. It is probable that the area removed comprised the upper part of the ascending frontal and parietal convolutions, and anterior part of the parietal lobule and the adjacent portion of the marginal convolution.

*Pathological Diagnosis.*— Round and spindle-celled sarcoma.

*Subsequent History.*— Considerable shock from the operation. Improvement in general condition. Motor aphasia, paralysis of right arm and leg. Two or three days following operation,

[1] Sub-cortical glioma of the cerebrum, affecting principally the arm centre; removal; recurrence of the growth; second operation; recovery. University Medical Magazine, January, 1895, p. 253.

[2] A case of sub-cortical, cerebral tumor treated by operation. British Medical Journal, January 5, 1895. Being "a paper read at a meeting of the Medical Society of London, on November 26, 1894. The patient was present at the meeting in good health."

attacks of clonic spasm involving right angle of mouth. After this, uninterrupted convalescence with improvement of paralyses. A month and a half after operation mental condition much improved. No aphasia; no paralysis of face; could raise right hand to chin; fingers paralyzed. Could walk with slight assistance; movement somewhat impaired at ankle; no movement of toes. Sensation slightly impaired on right upper arm. Condition four months later, at time when paper was read: Speech perfect; no headache; mind perfectly clear; no facial paresis. Right arm improved, some rigidity of joints, various movements impaired, hand-grasp weak. Right leg impaired somewhat in function, but walks without assistance. Sensation normal.

In this case, although it is probable that the entire tumor was not removed, there was complete cessation of symptoms attributable to pressure, improved mental tone and a diminution in the severity of the paralyses.

In view of these two cases, it would seem that a more radical operation for accessible tumors should be practised than is commonly done. It is amply demonstrated by experience that tumors of the brain, and especially the infiltrating varieties of which we are speaking, are fatally progressive in character. It is no less certain that those parts of the brain affected by the new growth are gradually rendered functionless, while new areas are continually being involved. Could the disease be attacked earlier, as soon as a definite or highly probable diagnosis is made, and a radical operation, with complete excision of diseased tissue, done, it is at least possible that the records of cerebral surgery might be brighter. The fear of cutting into the cerebral cortex doubtless often deters both the consultant from urging, and the operator from attempting, an extirpation of the growth. Whatever the relation of the so-called cortical motor centres may be to movements of distant parts of the body, it is certain that it is a matter of indifference whether those centres be destroyed by a new growth or by surgical procedure so far as their particular function is concerned. If an arm or a leg be paralyzed by a cortical or sub-cortical growth, the excision of this area can work no conceivable harm more than has already been effected. On the other hand, such operations as the two cases before us show, may lead to a decided improvement of all symptoms, *including the paralyses*. The hope of ultimate cure is possibly not great, but it offers a definite and the only chance; could a gliomatous tumor be completely extirpated, we know of no pathological law which would in any way necessitate its recurrence.

The two cases quoted are examples of exceedingly bold surgery with brilliant outcome. In both cases a conscientious attempt was made to eradicate all the diseased tissue, regardless of what centres might be included in the process. Sufficient time has not elapsed to make definite statements as to the ultimate outcome of these cases, but the result after a number of months is such as to justify the opinion that, if tumors of the brain are infiltrating and not encapsulated, they are not therefore to be regarded as inoperable. The localization of new growths in the motor cortex along the fissure of Rolando has often been regarded as a contraindication to extirpation, for fear of destroying motor centres with consequent inevitable paralyses. That such paralyses do occur after destruction of certain cortical areas is amply proved clinically, but of the possible restitution of functions after operation in the human subject we know much less. Goltz's[1] most recent experiment is of great interest in this connection. After various more or less successful attempts, he has finally succeeded in extirpating both cerebral hemispheres in a dog, with complete recovery from the operation. The dog lived for eighteen months, and was then killed to satisfy sceptics of the completeness of the original extirpation. During these eighteen months the animal was in no way paralyzed. In fact his motor activity was increased rather than diminished, and his capacity for performing elaborate co-ordinated movements remained unimpaired. The animal's psychical life and other details are of extreme interest, but do not concern us at present. Of importance to the present discussion is the lack of motor paralysis in spite of the fact that all so-called motor centres were destroyed. Of almost equal interest is an experiment of Malinowsky, alluded to by Goltz. This experimenter produced an abscess artificially in the left hemisphere of a dog, with resulting right hemiplegia. After the paralyses were well established he excised the abscess completely. The next day the dog had recovered from his hemiplegia.

It is not the purpose of these remarks to enter into details or theoretical considerations regarding the explanation of these phenomena. The facts at least are positive. To Goltz they seem the final blow to cerebral localization. However that may be, we must welcome conservative investigation, which tends to hold somewhat in check our overwillingness to attribute an excess of function to the cerebral cortex. The cortex is not essential to the performance of co-ordinated movements in the dog — that Goltz has proved beyond cavil — and yet unquestionably the cortex in the dog as in man is in some way associated with movement, probably with its voluntary performance. Malinowsky's experiment is, in its way, as striking as Goltz's hemiplegia apparently cured by excision of the area which previously, as an abscess, had induced the hemiplegia. The bearing of these facts on cerebral surgery is not altogether easy to estimate. Malinowsky's experiment would seem to indicate that an irritant like pus is much more detrimental to functional activity than a definite loss of cerebral substance. This may well have some application in the human subject, and especially to the class of tumors which we are considering. May not a vascular glioma with constant tendency toward softening lead to a much wider disturbance of cerebral function than a loss of an equal amount of brain tissue would do? And may not the character of a new growth be of more importance than has generally been supposed? Malinowsky's experiment renders such suggestions not unreasonable.

Goltz's radical experiment must at least force upon us the conviction that it is conceivable that human beings as well as dogs might get on much better than

[1] Pflüger's Archiv für die gesammte Physiologie, Bd. li.

has been generally supposed possible, with considerable loss of cerebral substance, even were that loss along the motor areas. Paralyses there would doubtless be, at least temporarily. That is a commonplace of observation. We know less of what the future might bring forth. The theories of physiological transference of function and all the problems which that involves cannot find discussion here. We would only suggest that Goltz's dog should be a constant reminder to us that our knowledge of cerebral function is quite in its infancy and that our enthusiasm for localization as a clinical aid, should not blind us to the possibility of its decided modification as a demonstrated fact.

The conclusions to be drawn are (1) that cerebral gliomata and infiltrating tumors generally should be removed surgically and as completely as possible; (2) that this procedure is not contraindicated by the localization of the tumors in the motor areas.

## THE ANNUAL REPORT OF HARVARD COLLEGE, 1893–94.

The annual report of the President and Treasurer of Harvard College is really the annual report of Harvard University. It covers the academic year from September 28, 1893, to September 27, 1894, and contains in addition to a report upon the academic department, reports from the deans of the various schools which make up the university. It is the reports of the Medical, Dental and Veterinary Schools which especially interest the medical reader.

In his personal report President Eliot calls attention to the change which the last fifty years has brought about in the relation of the college to the university, first, in the proportion which the number of students in the college bears to the whole number of students in the university; and, secondly, the relation of the required period of residence for the degree of Bachelor of Arts to the periods required for the other degrees given by the university. The percentage of Harvard College students in the whole university rose from a minimum of 42 in 1844–45 to a maximum of 65 in 1882–83, and from that maximum has steadily declined to about 50 in 1894–95, which is the percentage existing between 1850 and 1856 and again in 1868–69. In the mean time, since 1872 a residence of one year has been required for the degree of Master of Arts, whereas before none was required; between 1869–86 no less than seven degrees have been added to those previously provided for by the university; the required term of residence has been increased for the following degrees: for Bachelor of Science, from a variable period averaging about three years to a fixed period of four years; for Bachelor of Laws, from eighteen months to three years; for Doctor of Medicine, from three terms of about four and one half months each to four full years. President Eliot thus makes it clear, first, that the number of professional degrees has been greatly increased during the past thirty years, and, secondly, that the periods of residence for these degrees have been materially lengthened; and this lengthening of residence is particularly striking in the case of the two large professional schools — those of Medicine and of Law, and is even more striking in the case of the Medical School than in that of the Law School. On the other hand, the practice of admission to advanced standing in the college has lately increased; so that many degrees of Bachelor of Arts are now conferred every year upon persons who have not completed a residence of four years.

President Eliot considers it altogether desirable that the percentage of Harvard College students in the total number of students in the whole university should gradually diminish; for the other departments contain maturer, more advanced, and more serious students, and they should be fed by hundreds of institutions besides Harvard College, although that college should always remain their best feeder. He points out that such trivialities and crudities as still survive in the university naturally harbor in Harvard College; because the college only two generations ago was really a school for young boys. He thinks that gradually the influence of a large body of mature and earnest students who have a serious purpose in view is eliminating from the college itself these inconsistent survivals.

The resignation of Prof. H. P. Bowditch from the office of Dean of the Medical School after a period of service extending over ten years affords an opportunity to review the progress made by the school during that time. In 1883–84 there were 243 medical students; in 1893–94 there were 472 in attendance. During the same period the number of the faculty has increased from 22 to 28 persons, and that of other instructors from 30 to 58; a new building was occupied; the laboratory method of teaching was extended and improved; the activity of the school as a centre of medical investigation was fomented; the compulsory four years' course of study went into effect; the annual receipts and expenses of the school increased by about 75 per cent.

After June, 1896, either French or German must be presented in addition to former requirements for admission to the Medical School. All the professional schools of the university are gradually raising their requirements for admission, but these are in most instances still much too low. The laboratories of bacteriology and pathology have responded handsomely during the year to the increased demand which recent advances in medical science have made upon them.

The Dental School has had a prosperous year, and continues, through the devotion of its instructors, to make the most of limited resources. Though still hoping for a building of its own, it has nevertheless much improved and developed the building now occupied and loaned to the school by the Medical Faculty. Clever work to an increasing extent is done at this school in the treatment of cleft palates and fractured

jaws, and in one instance an artificial nose was constructed to the great satisfaction of the patient.

The Veterinary School has been steadily increasing the number of its students from year to year, and it is now proposed to raise the tuition fee from $100 to $150 a year. The expenses still continue to exceed the receipts, notwithstanding the fact that two of the instructors give gratuitous courses. The school needs an endowment, it needs a pathological laboratory and it needs a few scholarships for poor but meritorious students.

In an address delivered at the opening of the school year, September 27, 1894, Charles Francis Adams emphasizes the claims of veterinary schools and hospitals upon the community in such statements as these:

"An imperfect table shows in the Massachusetts of to-day 26 general hospitals, 21 special hospitals, and 12 church and corporation charities, besides dispensaries, all of them endowed, and containing some 8,000 beds, for the most part free. All the outcome of the last fourscore years — the immensely larger part of it the outcome of the last twenty-five years. A magnificent showing!

"So much for human ills. Now, turn to the other side of the ledger and foot up the column, and see what has been done for our brother — the brute. The total endowment foots up $2,800!

"So I am here to-day to plead, in an incidental way and with the liberally disposed, the cause of our dumb brother. His flesh, too, is heir to many ills; and he cannot describe them. He suffers in silence. Now in our Commonwealth much, as I have shown, has already been given, much is now being given to worthy public uses. We see its results in our daily walks in public buildings, in libraries, in parks, and in the beds of hospitals — it is all good; but, in this giving, why nothing to man's beloved companion and faithful servant?"

Again, another statement from this pithy address:

"In Massachusetts there are stated to be at this time some 200,000 horses and as many neat cattle. I have not looked into the census figures under the headings of dogs and cats. For the clinical treatment of these, if I may use that scientific expression, there exist to-day two public hospitals in Boston, with accommodations for about 65 horses and cows. Under such circumstances it is, indeed, frightful to think of the preventable suffering which must day by day be undergone by domestic animals, as well as the pecuniary loss to man thereby involved. . . . What more acute or greater satisfaction could any man or woman well have or desire, than to feel that through him or her the condition of the animal creation in the community in which the giver lived, had for all time been perceptibly improved and its sufferings alleviated?"

Tuberculosis, diphtheria, anthrax, hydatids, actinomycosis, and the long list of entozoa and parasites common to man and animals all testify to the intimate relation between their diseases, and to the importance of a comparative study of such diseases.

## MEDICAL NOTES.

The Sixth Congress of Balneology. — The sixth Congress of Balneology will be held at Berlin on the 7th of next March. Prof. Oscar Liebreich will preside.

The Successor of Sir Henry Acland. — Prof. J. Burdon Sanderson has been appointed Regius Professor of Medicine in the University of Oxford, in succession to Sir Henry Acland.

Prize Essay on Tuberculosis. — Dr. Herman Weber, of London, has given the Royal College of Physicians $12,500 for the foundation of a prize to be offered every two or three years for the best essay upon tuberculosis.

Cannot be Sent by Mail. — Bacteriologists and pathologists should take notice that by the new postal regulations, "disease germs and matters from diseased persons" are unmailable matter, and cannot in the United States be sent by post.

A Congress on Tuberculosis. — A national Congress on Tuberculosis is to be held at Coimbra, Portugal, beginning on the 24th of March, the anniversary of Professor Koch's announcement of his discovery of the tubercle bacillus.

Small-Pox in Dublin. — There have been 84 deaths from the present small-pox epidemic in Dublin, Ireland. The efforts of the sanitary authorities in dealing with the disease are said to have been far from efficient, owing to the fear of creating a scare, which, according to the *Medical Press*, means that they would rather let the paupers die than run any risk of spoiling the trade of the shopkeepers and lodging-house people.

An International Congress on Childhood will be held in Florence in the spring of 1895. Among the questions to be discussed are, the physical, moral, and mental elevation of children, children's hospitals, the care of deaf-mute and blind children up to the time of their admission into an educational institution, care of poor and abandoned children, reformatories, and vagabondage in its relation to childhood.

The Confusion of Tongues. — The date of the ninth International Congress of Hygiene and Demography, which is to be held at Madrid in 1897, has now been fixed from October 11th to 18th. The Spanish Government has sanctioned the use of no fewer than six official languages, namely, Spanish, Portuguese, French, Italian, English and German. At this rate international congresses bid fair to be excellent object-lessons in the "confusion of tongues." We hope that no hard feeling will be caused by the omission of Russian, Hungarian, Hebrew and Chinese from the list of official languages.

The Treatment of Variola with its Antitoxin. — Passed Assistant-Surgeon Kinyoun has reported to the Supervising Surgeon-General of the Marine-Hospital Service the employment of the blood-serum of a heifer calf, vaccinated four weeks previously, in the treatment of two cases of variola. Fifteen cubic

centimetres of the serum were injected subcutaneously when the cases came under observation, and again after the lapse of eight or ten hours. In one case four injections were made, in the other seven. A careful study of the cases, individually and comparatively, led to the conclusion that the treatment exercised a modifying influence upon the disease, especially upon the eruption. One of the cases died, but it is believed that life was prolonged at least seventy-two hours by the treatment. It is suggested that as the serum appears capable of mitigating the attack of variola it ought to have the power of rendering susceptible individuals refractory to the disease.

SENATOR GALLINGER ON ANTITOXIN AGAIN. — An editorial writer in the *Boston Herald* of February 6th, in speaking of Senator Gallinger's views on the future of antitoxin, made the following statement:

"It is shockingly bad taste that Senator Gallinger, of New Hampshire, displays in speaking slightingly of the medical profession of which he is the sole representative in the United States Senate. In voting an appropriation for the production of antitoxin in the District of Columbia his lay associates in the Senate showed considerably more respect for the science of medicine than the one person in that body to whom the public would most naturally look for an intelligent action on this subject."

The senator writes in defence of his position that he is in good company in his views, having on his side Dr. Hansemann, of Berlin, assistant to Professor Virchow, "the dean of modern pathology." The respect in which Professor Virchow is held by the medical profession, is so great that the announcement of his having been chosen to so important a position as that of the "dean of modern pathology" can hardly excite surprise. The fact that the distinguished "dean" himself holds views on antitoxin opposed to those of Dr. Hansemann, does not seem to have attracted Senator Gallinger's attention.

## BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, February 6, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 54, scarlet fever 51, measles 26, typhoid fever 5. During the week ending February 13th, there were reported the following cases: diphtheria 92, scarlet fever 43, measles 63, typhoid fever 2.

THE LYMAN PRIZE. — The announcement of the award of the Lyman Prize for this year was made by the Secretary of the City Hospital Club at its annual meeting. The amount of the prize is one hundred and fifty dollars in money, and it is open to ex-house-officers of the Boston City Hospital of not more than three years' standing. Six essays were offered. A first prize of eighty dollars was awarded to Dr. John Lovett Morse, of Boston, for an essay entitled, "A Clinical and Experimental Study of the Leucocytosis of Diphtheria." Two second prizes of thirty-five dollars each were awarded: one to Dr. F. A. Higgins and Dr. J. B. Ogden, of Boston, for an essay on "Traumatic Glycosuria," and one to Dr. J. B. Blake, of Boston, for an essay on "An Examination of some Recent Statistics in regard to Ether and a Consideration of Some Present Methods of its Administration." An honorable mention was given to Dr. A. B. Duel, of New York, for an essay entitled, "Leucocythemia, with a Report of Three Cases of the Splenic-Myelogenous Form." The practice of splitting up this prize into minute fractions may be a kindly one, but it seems to us a mistaken practice. It will be surprising if it does not tend to diminish both the number and the quality of the essays offered. The full sum is not an excessive reward for a first-rate piece of work. It can hardly be the object to encourage anything less than first-rate work.

PRESIDENT ELIOT STIGMATIZES FOOTBALL. — The President in the annual report of Harvard College, pays his compliments to football and takes very positive ground against it as an intercollegiate sport; to him it has become perfectly clear that the game as now played is unfit for college use and that it is impossible to make it fit. We have already discussed football enough, and see no reason to change the views previously expressed. If the *players wish* to reform the game, it can be made not only a fit but a very desirable game for college and inter-college use; if they do not reform it, why then it will doubtless be abolished. After our editorials of November 29th and December 6th, which attracted some attention throughout the country, we received a friendly and appreciative letter from Hon. Theodore Roosevelt, expressing in large measure the sentiments since uttered by him at the recent meeting of the Harvard Club in Washington. Mr Roosevelt does not overestimate the value of a few bones; he believes that Harvard College should produce men first, students afterwards, but that the two are compatible; he threatens to disinherit his son should that lad ever be found weighing the possibility of a broken bone against the glory of being chosen to play on Harvard's football eleven. Should young Roosevelt ever incur this mark of parental displeasure, we would feel that the responsibility lay at President Eliot's door, for one extreme begets another. In the mean time President Eliot has fled to Egypt, and the junior Roosevelt is not yet eligible to the team.

## NEW YORK.

ABATEMENT OF DIPHTHERIA. — Dr. H. M. Biggs states that during the past month the number of cases of diphtheria reported has fallen off 25 per cent., and he attributes this result to the use of antitoxin.

THE NEW YORK ACADEMY OF MEDICINE. — At a meeting of the New York Academy of Medicine held February 7th, Dr. Daniel Lewis was elected one of the Vice-Presidents, to fill the vacancy caused by the election in January of Dr. Joseph D. Bryant to the Presidency.

MORTALITY OF NEW YORK CITY. — Notwithstanding the extreme cold of last week there was some decrease in the mortality of the city, the number of

deaths reported being 921, against 952 during the week ending February 2d. The average for the corresponding weeks of the past five years is 879. There were 60 deaths from influenza, a decrease of 11, and the number of deaths from pneumonia also decreased. There was a slight increase of deaths from diphtheria, the number being 39, against 33 in the preceding week.

## Miscellany.

### THE FIRST SYMPHYSEOTOMIES IN AMERICA.

A THOROUGH and exhaustive investigation, conducted by the *Medical News*, in conjunction with Dr. R. P. Harris, seems to confirm the claim of Dr. J. O. Williams, of William Penn, Texas, to the performance of the first symphyseotomies in America.

The first operation was performed on April 29, 1880, on a girl thirteen years old. The child was illegitimate, and Dr. Williams had been urged by the parents to perform an abortion. He refused, and obtained the consent of the parents to allow the pregnancy to come to term on the condition that he would then secretly deliver the child. After a labor of eighteen hours, with no progress, the idea spontaneously occurred to Dr. Williams of separating the pubic bones by means of a tenotomy knife. He did the operation unassisted, and then delivered by forceps a twelve-pound child. A pelvic band was worn for six weeks, and mother and child did well.

The second operation was done in July, 1884. Dr. Williams, being unsuccessful in an attempt at the subcutaneous operation, performed open section. It was, however, necessary to perforate the head in order to effect delivery. A pelvic band was applied, and the mother was up on the twelfth day.

The third operation was performed in May, 1889, upon a negress, who had been in convulsions thirty hours, and had suppression of urine. The mother died, but the child lived.

Numerous letters and sworn statements support Dr. Williams's claim to the performance of three operations; in other words, to having spontaneously conceived and three times performed this operation before any other American surgeon. The comments on the operator and his work made by the *Medical News* are so good that we are glad to quote them:

"He was frankly deficient in preliminary education, and placed in a frightful tangle of most distressing and possibly tragic circumstances, no hint of which we have been able to give. He was surrounded by a set of conditions the dramatic interest of which we have scarcely seen equalled upon the stage. Through it all he has carried himself, and out of it all he has brought himself, with a combination of shrewdness, modesty and probity beyond all praise.

"The chief lesson to be learned from these cases has been summed up in the expression of Dr. Harris: 'In your reports and statistics, wait until you hear from the backwoods.' 'The backwoods' are often deficient in literary qualities, and in many of the arts of modern medicine, 'push' and self-assertion included; but they are often profoundly ingenious, and not seldom exhibit an unchronicled heroism quite equal to any that vaunts itself in populous places."

## Correspondence.

### A NEW JOURNAL DEVOTED TO THE DIGESTIVE ORGANS.

BALTIMORE, February 11, 1895.

MR. EDITOR: — The rise of a specialty in medicine is marked by the appearance of journals especially devoted to it. We are glad to inform you, that the new specialty of "Diseases of the Digestive Organs" is about to have its own publication — the *Archiv für Verdauungskrankheiten*, which will appear in April. It will be published in Berlin, Germany, by S. Karger. The editor is Dr. I. Boas, the well-known author of a work on "Diseases of the Stomach." He will be assisted by specialists in Germany and other countries. The *Archiv* will contain original articles, besides reviews and abstracts of recent literature, and will embrace diseases of the stomach, intestine, liver, pancreas and peritoneum, constitutional diseases and dietetics. Those interested may communicate with the editor or the publisher.

Yours truly, JULIUS FRIEDENWALD, M.D.

### MORPHINISM IN CHILDREN.

BROOKLYN, N.Y., February 1, 1895.

MR. EDITOR: — I am desirous of adding to the clinical literature of morphinism in children. If any reader of the JOURNAL has met with a case, and will furnish me details, I shall appreciate the favor, and give full credit.

Respectfully, J. B. MATTISON, M.D.

### RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, FEBRUARY 2, 1895.

| Cities. | Estimated population. | Reported deaths in each. | Deaths under five years. | Percentage of deaths from | | | | |
|---|---|---|---|---|---|---|---|---|
| | | | | Infectious diseases. | Acute lung diseases. | Typhoid fever. | Diphtheria and croup. | Scarlet fever. |
| New York | 1,956,000 | 952 | 315 | 8.69 | 27.94 | .22 | 4.18 | 1.10 |

| Waltham | 22,024 | 6 | 1 | — | 16.66 | — | — | — |
| Quincy | 19,642 | 9 | 3 | — | 33.33 | — | — | — |
| Pittsfield | 18,862 | 3 | 1 | — | — | — | — | — |
| Everett | 16,585 | 11 | 3 | — | — | — | — | — |
| Northampton | 16,331 | 4 | 2 | 25.00 | 50.00 | 25.00 | — | — |
| Newburyport | 14,073 | 3 | 0 | — | — | — | — | — |
| Amesbury | 10,920 | 6 | 3 | — | 50.00 | — | — | — |

Deaths reported 2,881: under five years of age 927; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 389,

acute lung diseases 641, consumption 335, diphtheria and croup 153, scarlet fever 41, typhoid fever 21, diarrheal diseases 21, whooping-cough 15, cerebro-spinal meningitis 12, erysipelas 12, measles 10, small-pox (Philadelphia) 2.

From diarrheal diseases New York 10, Philadelphia and Washington 3 each, Brooklyn, Boston, Nashville, Worcester and Lowell 1 each. From whooping-cough New York 4, Brooklyn, Boston and Worcester 2 each, Philadelphia, Washington, Cleveland and Nashville 1 each. From cerebro-spinal meningitis New York 6, Lynn and Malden 2 each, Worcester and Chelsea 1 each. From erysipelas New York 4, Providence and Nashville 2 each, Brooklyn, Boston, Cambridge and Lynn 1 each. From measles New York 5, Brooklyn and Providence 2 each, Pittsburg 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530, for the week ending January 26th, the death-rate was 18.7. Deaths reported 3,797: acute diseases of the respiratory organs (London) 324, measles 75, whooping-cough 69, diphtheria 56, fever 47, diarrhea 42, scarlet fever 35, small-pox (Birmingham and Liverpool 2 each) 4.

The death-rates ranged from 11.3 in Leicester to 28.0 in Liverpool; Birmingham 19.1, Bradford 14.7, Croydon 15.0, Gateshead 15.8, Huddersfield 16.3, Leeds 20.3, London 17.6, Manchester 23.1, Newcastle-on-Tyne 16.6, Norwich 20.4, Nottingham 17.9, Oldham 19.2, Portsmouth 21.8, Sheffield 18.3, Sunderland 20.4.

## METEOROLOGICAL RECORD,

**For the week ending February 2nd, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—**

| Date. | Barometer. | Thermometer. | | | Relative humidity. | | | Direction of wind. | | Velocity of wind. | | Weather. | | Rainfall in inches. |

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 2, 1895, TO FEBRUARY 8, 1895.

The extension of leave of absence granted CAPTAIN REUBEN L. ROBERTSON, assistant surgeon, is further extended fourteen days.

The leave of absence on account of sickness granted FIRST-LIEUT. JAMES M. KENNEDY, assistant surgeon, is extended one month on account of sickness.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 9, 1895.

C. P. BAGG, assistant surgeon, detached from U. S. S. "Mohican" and ordered to the Naval Hospital, Mare Island, Cal.

F. G. BRATHWAITE, assistant surgeon, detached from Naval Hospital, New York, and ordered to examination preliminary to promotion.

JAMES STOUGHTON, assistant surgeon, ordered to examination preliminary to promotion.

## SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.— A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday evening, February 18th, at 8 o'clock.

Dr. C. F. Withington will read on "The Antitoxin Treatment of Diphtheria."

Dr. M. H. Richardson on "Intestinal Resection and Anastimosis" with cases.

JAMES G. MUMFORD, M.D., *Secretary.*

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday evening, February 20th, at 8 o'clock.

Dr. J. H. McCollom: "Observations on Diphtheria."

Dr. Richard Hogner: "Intra-Venous Medicated Injections, according to Prof. Guido Baccelli's Method."

JOHN L. AMES, M.D., *Secretary.*

THE AMERICAN ACADEMY OF MEDICINE.— The twentieth annual meeting will be held in one of the buildings of the Johns Hopkins University, Baltimore, on Saturday, May 4, and on Monday, May 6, 1895. The "headquarters" of the Fellows of the Academy and the meetings of the Council will be at the "Stafford."

Members preparing papers are urged to send a copy of the paper, or an abstract, to the Secretary as soon as possible, in order that time may be given him to prepare the press-reports. Members contemplating the preparation of papers, should give notice at once to the Secretary, as the completed programme must be issued early in April.

## HARVARD MEDICAL SCHOOL.

### EVENING LECTURES.

The next lecture will be given on Thursday evening, February 21st, at 8 o'clock, by Asst. Prof. M. H. Richardson. Subject, "A Consideration of Intestinal Obstructions, Acute and Chronic, with Technique of Resections." Physicians are cordially invited.

## APPOINTMENT.

DR. J. L. HILDRETH, of Cambridge, has been appointed by Governor Greenhalge, a member of the Massachusetts Board of Lunacy and Charity, *vice* DR. R. M. HODGES, resigned.

## RECENT DEATHS.

JONAS COWDRY HARRIS, M.D., M.M.S.S, died in Arlington, February 10, 1895, aged seventy-five years.

FREDERIC AUGUSTUS SAWYER, M.D., M.M.S.S., Vice-President of the Massachusetts Medical Society, died in Wareham, February 10, 1895, aged sixty-two years.

## BOOKS AND PAMPHLETS RECEIVED.

Notes on the Sanitary Condition of Mexico. By G. P. Conn, M.D., Concord, N. H. Reprint. 1894.

A *Résumé* of Twelve Hundred Examinations for Life Insurance. By William H. Dukeman, M.D., of Los Angeles, Cal. Reprint. 1894.

The Droitwich Brine Baths as Therapeutic Agents in Various Diseases. By W. M. Tomlins, L.R.C.P. (Lond.), M.R.C.S. (Eng.). Reprints. 1895.

### BRIEF MENTION OF A FEW CASES OF NERVOUS AND MENTAL MALADY INVOLVING MEDICO-LEGAL QUESTIONS.[1]

BY IRVING C. ROSSE, A.M., M.D., F.R.G.S., WASHINGTON, D. C.,
*Ex-Professor of Nervous Diseases, Georgetown University; Membre du Congrès International d'Anthropologie Criminelle, etc.*

I PURPOSE to submit for consideration a few cases which I trust may be sufficient to claim the attention of those having interest in forensic medicine. While not so interesting perhaps as the discussion of some current popular medical theory, the record of a few well-selected typical cases occurring in one's own work has, to say the least, more instructive and more immediate practical value.

In the case of disputed wills, where we are often called on to help settle the question of testamentary capacity of the testator, there is among lawyers of the present day a disposition on one hand to invalidate a will on account of the existence of mental states which would not be regarded as insanity from either a legal or medical point of view; while, on the other hand, the tendency is to be governed rather by the provisions of the will itself, and to maintain its validity, even in certain cases of insanity, when the provisions of the deed are rational. Inmates of asylums have made valid wills; and in the case of a testator who committed suicide within three days after its execution, the will was held to be good.

An attorney engaged my services some time since in a matter of the kind where a wealthy retired army officer had died and willed quite a large fortune to the Society for the Prevention of Cruelty to Animals. Searching the medical and military record of the deceased it was found that he had suffered from a specific trouble, and on one occasion was declared insane by a court-martial. This, with other evidence of a damaging kind, led the adverse party to offer a compromise, which was finally accepted.

A case of the same nature was that of a wealthy retired manufacturer from Massachusetts, whom I treated in May and June, 1893. He originally consulted me for obscure nervous symptoms resembling those of locomotor ataxia. A previous case of the kind suggesting diabetes, led to a urinary analysis which confirmed the diagnosis. For a time the patient did well under treatment, but during a summer holiday he fell into the hands of an irregular practitioner, and died suddenly, after willing his entire fortune of several hundred thousand dollars to the Baptist Church. On taking steps to contest the will, an inventory of the past habits of the deceased led to a satisfactory compromise.

The question of civil incapacity may also affect life insurance policies, as it did in the case of one of my patients, a hotel man, who died some time since of melancholia, when the company in which he was insured withheld the amount from his widow. The matter was, however, adjusted through the favorable medical representations that I was able to make.

Divorce and separation also come within the province of the medical legist. In June, 1892, I had a buxom-looking woman for a patient, who had been treated with indifferent success by several New York neurologists. She was one of those strange hysterical cases just along the border-land of insanity, such as I have attempted to portray in a paper read at the Jefferson Medical School a few years since.[2] Inquiry led to the significant fact that she was married to a very old man, and that she suffered from nymphomania. The case resulted in separation and ultimate divorce.

Another case of a very puzzling nature lately occurred in one of my patients whose domestic infelicity and jealous rage showed itself in periodic attacks to destroy fragile objects. On various occasions she destroyed several thousand dollars worth of valuable glass and china from motives of revenge toward her husband, whom she accused of unfaithfulness. After the most rigorous examination I was unable to establish insanity in this case, although a separation seems to have taken place on that ground.

A sociological problem seems to be involved in that of kleptomania, which like many other questions of the kind lies close to civil government. In cases of alleged "shop-lifting" it is often a very difficult and delicate thing to decide whether the alleged act is criminal or the result of an insane and uncontrollable propensity to pilfer, such as sometimes occurs in epileptics, neurotics, and in pregnant or hysterical women. While much is to be said on the side of the shopkeeper, medical intervention is often necessary for the ends of justice. A case occurred several years ago in Washington of two highly respectable ladies who in shopping were arrested and rudely treated for the alleged theft of a small article which a detective did not find on searching their persons. Being released, they had the detective arrested and fined, and brought suit against the firm. One of these ladies I attended through a prolonged attack of nervous prostration, the result of the shock, and when the trial came off I testified in her behalf. The jury saw fit to give her a verdict of ten thousand dollars.

Another question, in which a considerable amount of the currency of the country is involved, occurs in the case of one of my patients who dates his breakdown from the disaster at the old Ford's Theatre. Although he was not visibly or outwardly injured by the accident, yet he claims that from being well and strong immediately before the accident he has become a neurasthenic invalid unable to do business, and claims a money compensation therefor. The matter, being investigated by a Congressional committee, is still in abeyance.

But of all the neurological cases in which knowledge is brought to bear in a medico-legal way those involving the money compensation of invalid pensioners are the most unsatisfactory. From a scientific point of view nothing can be more difficult to adjudicate than alleged disabilities plus the element of politics. It is therefore not to be wondered at that many of these cases are in a hopeless muddle. In a paper read at a meeting of the American Neurological Association at Long Branch in 1877, I attempted to show a few of the errors of diagnosis in such cases.[3]

My principal object, however, in mentioning this paper is to call attention to a case of aphasia, already reported in the *Virginia Medical Monthly* of July, 1890. The case merits particular study for the reason that this man having committed a criminal offence and being sentenced therefor, a question arises as to his

[3] Journal of Nervous and Mental Disease, November and December, 1887.

responsibility. Many new features of aphasia in its medico-legal relations have lately been treated in an able article by my friend, Dr. Charles K. Mills, of Philadelphia.

Of the great number of claimants for pension that have come to notice, many of the alleged disabilities are about as doubtful in a neurological way as the cases of chronic diarrhea contracted in the Chickahominy campaign in subjects who are fresh-colored, apparently well-nourished, and weigh over two hundred pounds at the present time.

Such cases of malingering are hardly so much to be wondered at as that of a Washington clergyman, who like many of his class gives certificates to quacks and charlatans. This man, in a newspaper advertisement, stated that a certain charlatan had cured him of a chronic disease. Yet, in order to get a pension from the government, this reverend gentleman came to me to be examined for the very disease that he claimed had been so wonderfully cured.

In connection with this subject I call attention to three cases in which the anatomical lesions are somewhat remarkable, although bearing but little on the nervous and mental condition. The first is an acromegalous condition of the right arm following a gunshot injury of the right subclavian; the second is a case of dementia in which occurs the anomaly of a double inguinal and femoral hernia; while the third case, in a man of unsound mind, shows a duopagous penis having a slit in the end with some of the characteristics of a vagina.

In the matter of malingering, the so-called litigation cases of the railway surgeon furnish some of the best examples of a psychological feature arising from the prospect of receiving money compensation for alleged injuries.

The only case of "railway spine" that I have ever seen, among an unusual number of railway injuries observed, was that of a patient who came to me in October, 1888, who stated that his disability was the result of a railway accident at Pope's Creek, Va., in June, 1888, and that he had instituted a suit for damages against the road. The symptoms disappearing rapidly under the treatment, I was obliged to tell his attorney that, unless he soon brought the case to an issue, my testimony for his client would be very weak. On hurrying the matter, the road compromised at seven thousand dollars, and I waited a long time for that "handsome fee" the patient had so often promised. But, alas for poor human nature! I had to bring suit. The plaintiff employed a *sundown*[1] "shyster" lawyer and gave perjured testimony; all of which, however, did not prevent my getting judgment and eventually my money.

Another case of alleged spinal injury was seen by me several times in Fredericksburg, Va., in January, 1893, at the request of the Pennsylvania Railroad Company. I found the patient neurasthenic and hysterical, and with Dr. Morton of Philadelphia, subsequently ascertained that the slight lateral curvature of the spine was owing to asymmetry of the lower limbs. The curvature disappeared on placing a book under the right heel so as to equalize the lower extremities, the right being an inch and a quarter shorter than the left. A settlement being effected in Alexandria, the plaintiff, who walked markedly lame on crutches before signing a release and receiving a check, immediately thereafter walked out of the room without crutches or lameness. She was married shortly afterwards, and, up to last accounts from Dr. Martin of Fredericksburg, was in good health.

A third case of spinal injury in a man, which I have had under treatment since August 11th, was not so fortunate in the way of money compensation. The injury occurred several years ago on one of the western roads, but he failed to secure damages, owing to a legal technicality. At present there is unnatural prominence of one of the injured dorsal vertebræ; he is paraplegic, and has great difficulty with his bladder.

Although the foregoing cases touch medico-legal points that are particularly delicate and obscure, their consideration is hardly invested with the same degree of interest or forensic importance as that of many cases calling for inquiry into the mental condition.

Some time ago I was summoned to appear as a witness before a court-martial assembled at the Artillery School at Fortress Monroe, Va., for the purpose of trying an accused for a grave military offence. After the usual preliminaries, I was asked by the judge-advocate whether or not I considered the accused insane, which question I declined to answer, but stated that I would tell what I had noted in regard to the physical state and conduct of the accused, and the court might draw therefrom its own conclusion. To this there was no objection; when my testimony as to hospital record, insomnia, a horse-kick on the head and subsequent queer conduct, suddenly ended the trial. The accused was declared insane, and sent to the Government Asylum at Washington.

It is, however, not such plane-sailing in many other cases, especially those in which insanity is entered as a plea in extenuation of a crime or misdemeanor, or where the object is to sequestrate a person in order to get control of money or estate, or to bring an end to unpleasant domestic relations, as shown in the following cases:

An employé of the Post-Office Department, being accused of embezzling thirty thousand dollars, his friends tried to establish insanity as a defence, and I was accordingly employed to conduct the examination. A most searching scrutiny into the patient's antecedents, as well as his present physical and mental state, failed to reveal a single fact to build upon. At my suggestion a physician from the Government Hospital for the Insane was called, who came to the same conclusion, when we abandoned the case. But a few days later two physicians were found who certified to "melancholia," when the man was sent to St. Elizabeth, where he remained a few months. The affair blowing over he was released, to become a cashier in a business establishment, which position he managed with all the care and propriety of a man in full possession of his faculties. He died a short time since from an overdose of narcotic medicine.

In another case, of a woman whose husband wished to get rid of her on the ground of insanity, I failed at three different examinations to find the least clue to the alleged condition, and consequently failed to sign a certificate. I learned, however, that the parties were living a cat-and-dog life, aggravated by violent temper on the side of the woman and general worthlessness on that of the husband, who wished, by putting his wife in an asylum, to get control of a few thousand dollars. Subsequently, two doctors certified to this

[1] One regularly employed in a Government bureau, and practising a profession after office hours.

woman's insanity, when the sanitary officer from the police headquarters, whose province it is to look after such cases, proceeded to take her from home. Being an experienced man in such matters, and having personal cognizance of the facts of the case, he ended the matter by refusing to take her to the asylum.

I was called in consultation to a similar case only a few days ago. Exhaustive examination failed to reveal any delusion or mental weak point on the part of the woman, whose tale was the old one of unfaithfulness on the part of the husband, her own ungovernable temper, and consequent domestic infelicity. To all appearances the woman was the saner of the two.

In 1890 I was requested by a prominent attorney in Washington to visit one of his clients, who was in jail under indictment for murder. He was alleged to be breaking down physically and mentally, and for this reason it was desired to secure his release on bail. A series of visits extending over several weeks did not impress me favorably with the case. But in view of the prisoner's evident failing health, albuminuria, insomnia, fibrillary twitchings, pulse 120, and extravagant and incoherent talk, I testified in substance that he was not in condition to undergo trial and that upon further incarceration he would grow progressively worse. The court taking this view of the situation released the prisoner upon bail, which was said to be a case without precedent, since prisoners indicted for similar offences are not bailable. The accused being able to work up a satisfactory defence, was acquitted. He resumed his dissipated habits, and was finally killed by an electric car, but whether the result of accident or suicide has never been determined.

About the same time that this trial was going on, I was called to the Twelfth-Street Police Station to examine into the sanity of a gentleman from one of the neighboring counties of Virginia. It seems that for several days he had been negotiating for most of the valuable property in Washington, and had already bought up all the best hotels, for one of which he gave a cheque for $500,000 on a bank in which he had no money. I was affably received by the prisoner, who told me in a complacent way of his enormous money transactions, and ended by saying that he had been put off a street-car because he had not five cents to pay his fare. When asked why a man of his great wealth should want for such a small sum, he was nonplussed and did not attempt to explain. My chief reason for mentioning this case is that it illustrates so well in a clinical way the delusion of grandeur — a prominent mental characteristic of general paresis, and moreover, a symptom that caused no hesitation in signing the necessary certificate to enable the friends to provide for sequestration and treatment of this unfortunate man.

On October 25, 1891, I was requested to visit the Government Hospital for the Insane in order to examine a naval paymaster, whom it was desired to release by the proper legal proceedings. The patient had been addicted to alcohol and opium, but seemed clear and rational on all points, and even passed a fair examination in mathematics until he got to the binominal theorem, which he tried to explain in a letter to me next day. I produce the letter herewith, because it was one of the principal points upon which I differed with my esteemed friend Dr. Godding, who testified at the inquisition that he thought the handwriting indicative of general paresis. I thought otherwise, for the reason that the patient had broken his leg some time previously and being obliged to use artificial support in walking had contracted crutch paralysis, which he said had so affected the arms and fingers as to cause the peculiarity you here see in the letter. Besides, I had at the time a perfectly sane patient, the Register of the United States Treasury, General Rosecrans, whose chirography was similar. The Episcopal Bishop of Maryland had, moreover, the same peculiarity in a marked degree, and I have never heard of his being insane. The court was evidently of my way of thinking; for the petitioner was released. He led a correct life for some time afterward, but unhappily he took an overdose of laudanum before the days of permanganate of potassium, and died at a hotel in New York.

On January 28, 1893, I visited the district jail with Dr. Godding to inquire into the mental condition of a young man under sentence of death for the murder of his wife. This celebrated case, known as the *Schneider Case*, was attended by great public excitement: the inquisitorial procedure conducted by three judges was a long one, and the testimony was voluminous. From what was learned of the prisoner's antecedents and his condition I did not hesitate to express my opinion that he was a paranoiac. The court, however, thought the prisoner feigning, and allowed the law to take its course. Events following the inquiry up to the moment of the prisoner's execution, as well as the post-mortem findings, corroborated the diagnosis and leave serious doubt in the minds of many persons. A more detailed account of this case is found elsewhere.[5]

On March 26, 1894, I was summoned to testify as to the sanity of a young man accused of arson. From the attending physician I learned that he had never fully recovered from the effects of typhoid fever, that he suffered from sexual hypochondriasis, and had attempted suicide with strychnia. It required but slight inspection to satisfy one of the poor physical condition and mental incoherency of the accused, and of his inability to choose right from wrong. The court certified him to the Secretary of the Interior for confinement in St. Elizabeth, where he remained some time; but after release he again attempted suicide in Alexandria on two occasions, when he was sent to the asylum at Staunton.

July 28, 1894, I testified as to the capacity of a business man of Washington regarding whose property there was considerable family friction. The patient was stuporous, apathetic, and uncommunicative, and as far as I could learn was suffering from alcoholism. I opposed sending him to an asylum for the reason that it would worsen his condition. After an attorney had harangued the jury for some time with the usual antiquated "chestnuts" as to the worthlessness of expert medical testimony in such cases, the defendant was declared insane. But on being allowed to take an outing with a companion he promptly recovered, as I said he would. He was released, and is now attending to business.

Medical witnesses in such cases are often placed in an unfavorable and unjust light by the tactics resorted to by lawyers and approved by the courts. The expert being in no position to reply, the jury and the public hear only what the lawyers have to say. Aside

[5] The Journal of the American Medical Association, February 2, 1895, also Virginia Medical Monthly, February, 1895.

from giving a blurred and distorted character to medical knowledge with which they are imperfectly acquainted, some inexperienced and superficial lawyers avail themselves of the unfair method of quoting antiquated authority in denunciation of expert opinion. While this is an unfairness frequently taken advantage of by lawyers, we seldom hear a medical man say, "A mere judge's opinion, worth nothing, and carries no weight." Yet error is inseparable from human procedure, and lawyers and courts often differ as to questions of fact, and even make mistakes by advocating false theories embodied in legal propositions.

Error and contradiction are not confined to the medical profession alone. Even in such a simple matter as lowering the topmasts of a ship to pass under the Brooklyn bridge, eighteen experienced persons testifying before a commission a few years ago, gave as many opinions, no two of which agreed.

Lawyers, being only human, are liable to error of judgment and difference of opinion. In fact, it is said that lawyers exist as a class only because they see differences in the same occurrences, and judges are found frequently disagreeing upon points apparently less recondite than the mental state of an alleged lunatic. Lawyers would scarcely be prepared to admit that legal decisions are worthless because three judges unanimously on appeal decided a case in favor of the defendant which three other judges in an inferior court had as unanimously decided in favor of the plaintiff, precedents for which may be readily cited.

The object of all legal inquiry is the truth; yet no less a person than Chief-Justice Coleridge of England, speaking of a book of celebrated legal decisions, says that the community would be none the worse off if all the cases therein mentioned had been decided the other way, and Sir James Stephen says that "The criminal law does not deal with truth."

Cases may be cited almost indefinitely showing the disagreements of judges and the fearful muddle that lawyers have made with plain matters of fact. Thus, in King *vs.* The Victorian Railway Commissioners, three judges had to decide the comparatively simple question: "Is the putting of the head out of the window of a railway carriage in motion a reasonable use of the carriage?" with the result that two said yes, and one said no.

Again, four judges dealt with the filing of a bill of sale in Danby *vs.* The Australian Finance and Guarantee Company. That the bill was good three judges held, one for reason (*a*), one for reason (*b*), and one for reason (*c*), each seeing nothing in the reasons of the others, while the fourth judge held that the bill was bad, none of the reasons being, in his opinion, satisfactory. Another instance, even more suggestive, is that of Vagliano *vs.* The Bank of England. After passing through two courts in favor of Vagliano, the case was decided by the House of Lords in favor of the bank by six to two, no two of the majority agreeing as to their reasons. Despite this conclusion, we find on counting heads in all the courts, that Vagliano had eight judges in his favor. Yet he lost his case. To these instances might be adduced differences of opinion even in such a seat of authority as our own Supreme Court, reports from which show as many as thirty-five cases disposed of with as many different opinions, concerning which occur the familiar phrases, "Bench pretty evenly divided," "Reverses its own decision," etc., while, more curious to relate, is the late reversal of the opinion of Mr. Justice White by an Arkansas judge.[6]

In relation to criminal offences committed by the insane, the law, in applying its metaphysical test to determine the responsibility of those whom science states to be physically diseased, acts upon a theory which as a matter of experience medical men know to be utterly and hopelessly false. Yet the judge, to quote the words of eminent authority, sends to the jury a false theory, as in the old trials for witchcraft; the jury acts thereon; the judge tells the executive that the prisoner had a fair trial; the law takes its course, and the case is used to prop up the false theory in subsequent trials.

The certainty with which the law prides itself is, therefore, not shown in the application of the legal test, for a perusal of cases will show that in the matter of insanity the decision of the courts is often a matter of chance, dependent on the predilections of the judge or the sentiment of the hour.

Again, the legal habits of overlooking the physical basis that exists in insanity renders the legal test from a scientific point of view less than half a test. Applied to the irresponsibility of the insane it is wrong in theory, false in fact, cruel in its metaphysical conception, and unreliable in its practical application.

I am fully aware that the foregoing views will not meet the unanimous approval of my legal friends. But, let me ask, is the present method of procedure the best that keen legal insight and contemporary science can devise?

The great advance of medical knowledge in the last century, slowly pulling the law along in its wake, has even convinced learned judges of the absurdity and injustice of condemning innocent old witches to death, and as legal fictions disappear the time may come, we trust, when no intelligent lawyer will speak of "the vicious principle of considering insanity as a disease" or be guilty of quoting from an obsolescent volume, as some of them are fond of doing, that old chestnut of a down-East judge, who throws general discredit upon the opinions of medical experts with a force of judgment only equalled by that of Jack Bunsby.

## CASES OF PREGNANCY COMPLICATED BY HEART DISEASE.[1]

BY GEORGE G. SEARS, M.D.

CARDIAC lesions as a complication of pregnancy have not as yet received the attention in text-books which their importance demands, nor have the best methods of treatment in this condition been adequately discussed in them. This oversight has been partially corrected by monographs upon this subject, as well as by a number of papers which have appeared in the periodical medical press within the past few years, but as their conclusions have been chiefly drawn from cases which presented either very serious or unusual features, the gravity of the complication seems to have been, from the point of view of immediate results, as much overestimated in the latter as underestimated in the former. It is not an unusual experience in out-patient work for women to apply for relief of cardiac symp-

[1] To be published in the Sixth Series of the Boston City Hospital Medical and Surgical Reports.

[6] In the celebrated pension case of Long *vs.* Lochren, the decision of Judge Cox has lately been reversed by Judge Bradley.

toms whose lesions were undoubtedly present during one or more pregnancies and yet were the cause of no serious manifestations or were even unsuspected by both the patient and her medical attendant. A number of these cases have been selected for a brief report owing to the fulness of the records in several important points, including two which are given in somewhat fuller detail, who sought advice during the early months of pregnancy and whose course has been followed up to the present time.

CASE I. Mrs. P., thirty-five years old, pregnant for the fourth time. Except for vague pains in muscles and joints no rheumatic history was obtained and her general health had always been good. The birth of the first child was followed by mania from which she recovered after an illness of three months. The second and third pregnancies were uneventful, but early in the fourth she began to grow somewhat short of breath, and toward the end of the fifth month she noticed that her feet and vulva were swollen. On examination the heart was found to be laterally enlarged but its exact limits could not be accurately determined owing to the great development of the breasts. A very rough systolic murmur, loudest at the third left costal cartilage, was audible over almost the whole cardiac area. At the apex the first sound was somewhat muffled, but no other modification was noticed. The second pulmonic sound was markedly accentuated and a few fine râles were heard at the bases of both lungs. The urine was repeatedly tested but was always free from albumin. Her diet and mode of life were regulated so far as her circumstances would permit, and digitalis and general tonics were ordered. Her condition, if anything, improved somewhat during the next four months, although the edema still persisted. Labor came on at term and lasted about forty-eight hours, but the early pains were infrequent and so slight that they caused but little inconvenience. Active labor lasted but an hour and a half, and as the head steadily advanced and her condition remained good no interference was thought necessary, but ether was freely given. Except towards the close of labor, when it rose to 74, the pulse remained at 60, but it was soft and easily compressed. After the birth of the placenta it fell to 56. The post-partum loss of blood was normal. An examination of the heart made two weeks later showed the following condition: the apex was in the fifth interspace fully an inch outside the normal line, while the area of cardiac dulness extended two fingers' breadth to the right of the sternum. The same rough systolic murmur was still heard all over the precordia, with seat of maximum intensity over the sternum opposite the third costal cartilage. Toward the apex the murmur became much softer in character and could be followed outward into the axilla. The pulmonic second sound was accentuated and reduplicated. Her strength returned slowly but she insisted on getting up during the third week. Although complaining of dyspnea in climbing a few steps she remained fairly comfortable during the next three weeks, when she "took cold" and began to cough, raising thin, white sputum somewhat tinged with blood. Dyspnea so increased that she was unable to lie down. Her expression was anxious and the extremities slightly cyanotic. The chest was filled with medium and coarse moist râles and there was slight dulness at both bases. The pulse was irregular and weak. This condition persisted for about two months, with occasional remissions or exacerbations, one or two of the latter being so severe that stimulants were given hypodermically. She then began to slowly improve and is now able to attend to her lighter household duties, but dyspnea is still so marked that the ascent of a flight of stairs is attended with considerable difficulty. The baby at birth was a well formed and apparently healthy child, weighing seven and a half pounds, but it possessed no vitality and died of marasmus when four months old. The third child alone survives.

CASE II. Mrs. H., aged twenty-eight, had rheumatic fever about a year before the birth of her first child, six years ago, and again about four years ago. Her second child was born four years ago, and a few months later cardiac symptoms developed. Between this time and the birth of her third child, last October, she had three miscarriages artificially induced, all under four months. She first came under observation at the beginning of her last (sixth) pregnancy, complaining of palpitation, dyspnea and precordial pain. There was considerable lateral enlargement of the heart, a systolic murmur at the apex transmitted outward, and accentuation of the pulmonic second sound. There was neither albuminuria nor edema. Except for a slight increase in the dyspnea and a little swelling of the feet, she passed through her pregnancy without noteworthy occurrence. She was attended in her confinement by her family physician, who extracted the child by forceps after a seven hours' labor, without ether, delivery being followed by a pretty profuse hemorrhage. Four days later she had an attack of syncope, but without losing consciousness, and during the following week she had several similar attacks. Under a tonic regimen she has slowly improved, the murmur has diminished in intensity, and the heart itself has somewhat regained its tone, but she still complains of dyspnea, and seems to be living at a lower level than before the occurrence of this last pregnancy.

In both cases the history of previous easy labors, the comparatively slight severity of the cardiac symptoms and the absence of albuminuria, gave every reason to expect a favorable issue under treatment indicated for uncomplicated cases of failing cardiac compensation, and the immediate result justified the expectations. When, however, cardiac symptoms show a tendency to increase in severity, and the patient's condition begins to cause anxiety, it is questionable how far the expectant plan of treatment is justifiable in meeting a complication which, under such circumstances, is fatal in thirty-five or forty per cent. of the cases. In other complications of pregnancy, like uncontrollable vomiting or eclampsia, where the presence of the fetus is the immediate cause of danger, the necessity for emptying the uterus before the patient's condition becomes desperate is generally recognized; yet in both these conditions recovery, if it takes place, is complete, and there is but one risk to consider, while in heart disease, not only is the present danger very great, but, if this be successfully passed, the prolonged strain upon the weakened cardiac muscle is apt to permanently incapacitate the patient in a greater or less degree for any form of active life, and be the starting-point for a chain of symptoms which end in premature death. With two dangers to be considered, a remote as well as a present, it is difficult to understand why the same treatment should not have been

considered equally applicable to cardiac complications, unless it be that the induction of labor has usually been so long postponed that death has been wrongly attributed to the operation, when of necessity it was the only result to be expected. Within the past year a prompter resort to radical measures has been urged with more or less emphasis by several writers. Seolowjew,[2] for example, says that when ordinary methods fail, labor should be induced even in desperate cases. E. Leyden[3] is equally positive, and says that the results are so bad because it is postponed till too late. Allyn,[4] in speaking only of mitral stenosis as a complication, says that the frequent occurrence of spontaneous miscarriage or premature labor is "an indication that it should be induced when dangerous pulmonary symptoms persist in spite of suitable treatment." Webster[5] shows more conservatism in apparently taking the opposite view, when he declares that "the quiescent condition of pregnancy is less dangerous to the heart than the disturbance brought about by the emptying of the uterus," but gives no directions for continuing this quiescent state beyond the ninth month. If he means, as he probably does from a later statement, that when a patient's chances have become desperate, induced abortion may only hasten a fatal result, his position deserves little criticism, but should rather be emphasized, in order that she may be prevented from drifting into a condition where death is almost inevitable, no matter what is done.

So many outside considerations come up when the treatment of this complication is discussed, that the main issue becomes clouded, namely, that labor, so far as its effect on the heart is concerned, is primarily a succession of muscular efforts, whose length and severity, unlike voluntary exercise, can only be approximately estimated at best, and which follows a period in which the strength of an already weakened heart is steadily deteriorating. Unfortunately, the welfare of the mother cannot alone be thought of, since a second life is at stake for whose sake greater chances must be taken; but it is an open question if more consideration has not been given to the child, without benefit to either, than is warranted by facts. It is generally conceded that the expectation of life in children born of women with serious heart lesions is decidedly impaired; but the amount of impairment cannot be definitely given until more facts are at hand, reporters of cases not having sufficiently recognized the importance of giving the fate of the children. Beside the two given above, I have notes of five other cases which are complete in this respect, two of which have been reported in detail elsewhere, and will only be referred to briefly here.

CASE III. Mrs. C., thirty-two years old, suffering from double mitral lesion probably following chorea in childhood, has borne six children at term, and miscarried once at the fourth month. Excepting the first, marked cardiac symptoms were present in all the pregnancies. The third child alone survives, the others all dying within a few months after birth.

CASE IV. Mrs. B., thirty-six years old, had mitral regurgitation, probably due to an attack of acute rheumatism following the birth of the third child, but cardiac symptoms were first troublesome during her fifth pregnancy. The child lived but eighteen months. The sixth pregnancy terminated spontaneously at the seventh month.

CASE V. Mrs. M., aged thirty-five, vi-para, had chorea when fifteen years old, and rheumatic fever a year or two later. Marked symptoms of failing compensation appeared first during her fifth pregnancy, although there had been a little edema and dyspnea during the previous four, but not of sufficient consequence to require the services of a physician. The sixth child was born about three weeks ahead of time. The last two children lived but a few months.

CASE VI. Mrs. T., age thirty-two, iv-para, began to complain of dyspnea shortly after her marriage, eleven years ago; but cardiac symptoms did not become severe until her first pregnancy, eight years ago. Since then she has had three children, the last being born about one year ago. Attacks of syncope, dyspnea, edema of legs, cough, with sputum occasionally tinged with blood, were present in all her pregnancies, while in the latter part of the third she was unable to lie down. In all, menstruation recurred regularly during the first eight months, and after delivery hemorrhage was always so profuse as to "alarm the doctor." Forceps were used in every instance. The first child is living, but in the last stages of consumption. The second child lived three months, and died of convulsions. The third child, now five years old, is strong and well. The fourth died of some acute pulmonary trouble when two months old.

CASE VII. Mrs. H., aged thirty, iii-para, had an attack of rheumatism when twenty years old, and has since suffered from dyspnea on exertion, which has increased in severity since the birth of her first child about four years ago. The first pregnancy passed without noteworthy increase in symptoms until two or three weeks before the birth of the child, when she had a severe paroxysm of precordial anxiety and pain with loss of consciousness. These paroxysms have occurred at irregular intervals since.

The labor was very long, but terminated spontaneously, and was followed by a hemorrhage. The baby lived but fifteen minutes, the only assignable cause of death being the length of the labor. During the second pregnancy there was no increase in the dyspnea and no edema; labor was short, and the child is still living. She again became pregnant last spring, when the cardiac symptoms increased in severity and were accompanied by vomiting. As in the last case, the menses, though scanty, recurred regularly and led to a mistake in diagnosis on the part of the attending physician, whose efforts to relieve a congestion of the womb resulted in a miscarriage at the fourth month. At the time of examination the heart was found to be somewhat enlarged and a soft, diastolic murmur was heard at the fourth left costal cartilage transmitted toward the apex. At the apex the first sound was rough.

Leaving out of consideration the four cases of abortion, either criminally or accidentally induced, as well as the child whose death was probably due to a too protracted labor, these seven women were collectively pregnant thirty-one times. Of the fifteen children born before the cardiac symptoms became so severe as to require the advice of a physician, twelve are living and three are dead, while as a result of the sixteen other pregnancies but three children still survive, of whom one has but a few months more of life. The sharp contrast between the two sets is so marked that it can

scarcely be due to mere coincidence, and should anything like the same mortality rate, as seems not improbable, be found in a sufficiently large number of cases for definite conclusions to be drawn, much of the force of the most serious objection to an early resort to induction of labor would be lost.

In a paper on the same subject, published about a year ago, among other conclusions the following propositions were formulated: that the frequency of miscarriage and the doubtful fate of the child make the welfare of the mother the more important consideration in deciding the question of abortion; that the necessity for inducing abortion is very probable in the presence of grave symptoms in the early months, or of a progressive lesion, or of a history of great danger in the preceding pregnancy; and that when the necessity becomes apparent, the sooner it is done the better. Later experience, both with these cases and with a number of others, who applied for relief from cardiac symptoms dating from some previous pregnancy or shortly after labor, but whose records are, I regret to say, too incomplete to report here, has strengthened rather than weakened this opinion; but the special points which I wish to emphasize are the necessity for classifying heart-disease among other conditions in which the presence of the fetus is the immediate source of danger, in order that in this complication the same chance of recovery may be given to the mother which is accorded her in the so-called uncontrollable vomiting of pregnancy or in eclampsia, and that the remote effects of pregnancy and labor, as shown by impaired cardiac compensation, should receive the consideration which their importance demands in deciding the question of the induction of labor.

## CÆSAREAN SECTION, WITH THE REPORT OF A CASE.[1]

BY GEORGE HAVEN, M.D.

PELVIC deformity begins when the true conjugate falls below four inches, and the difficulty of delivering a living child through the pelvis at term increases as the diameter decreases, and becomes impossible when the conjugate measures three inches or less. The size of the child in all cases should be estimated so far as possible, and of special moment is the size, hardness and compressibility of the head. Delivery is accomplished in the lesser degrees of contraction by nature, forceps or version. In the greater degrees of contraction three methods are to be considered: first, emptying the uterus during the early months of pregnancy; second, induced labor at the seventh, or eighth month; and, third, the major obstetrical operations, namely, craniotomy, Porro, symphyseotomy, and Cæsarean section.

I do not wish in this paper to consider the subject of abortion, and shall confine myself to induced labor and the major operations. It is clearly our duty to select the operation which offers the best ultimate result for mother and child. How far respect for fetal life should determine the method is a matter to be decided by the family, operator, and in Catholic families by the priest. It is, however, safe to say that no operator will destroy fetal life if other methods of procedure offer which are equally, or almost equally, safe for the mother.

[1] Read before the Obstetrical Society of Boston, December 15, 1894.

Induced labor is by no means an absolutely safe operation for the mother, and the fetal mortality is very large. In twenty-three cases of induced labor, at the Boston Lying in Hospital, 19 children died. Selecting the cases which are on the records subsequent to the introduction of antisepsis, or, in other words, the cases occurring since 1885, we have one maternal death in 12 cases or a mortality of between eight and nine per cent. Dr. Theodore Wyder, in an exhaustive article in the *Archiv für Gynækologie*, Band 32, reports 225 cases operated upon since the introduction of antisepsis. Of these 12 died, or a mortality of 5.3 per cent.; and the fetal mortality in these cases was a little under 50 per cent. This is distinctly less than Winkle's estimate of 66 per cent. for the fetus. With our increasing knowledge of asepsis, I have no doubt that the maternal mortality can be reduced, but fear that it can never be eliminated. The fetal death-rate, with improved methods of caring for the child, may also be reduced but *must* remain very high.

Craniotomy is fatal to the child, unless we accept a report which comes from the West, where the brain substance was replaced and the child lived. The maternal mortality, quoting once more from Wyder, is about five per cent., and his table is made up of the following cases: 104 cases are from the Berlin Polyclinic, with six deaths, or a death-rate of 5.8 per cent.; 35 cases are from the Halla Clinic, with two deaths, or a death-rate of 5.7 per cent.; 76 cases are from the Leipsic Polyclinic, with four deaths, or a death-rate of 5.3 per cent.; in all, 215 cases with a mortality of 5.6 per cent. In the Lying-in Hospital there have been 15 perforations with one death, or a percentage of about six. The latest figures by Leopold place the mortality at two per cent.

I shall only speak of Porro's operation in passing, as the mortality is so high that I think it will only be undertaken in cases where hemorrhage cannot be controlled, or where for some other reason the Cæsarian section is contraindicated. The mortality in the United States, quoting from Dr. Robert P. Harris, is 61 per cent.; in Italy it is between 38 and 50 per cent., and in Germany it is claimed to be only a little above 10 per cent.

Symphyseotomy has already been spoken of by Dr. Jackson, and his paper has so exhaustively and so ably treated the subject that it leaves nothing for me to add. This brings me to the subject of my paper, Cæsarean section.

Schrœder says, that the first authentic case of Cæsarian section was that of Trautmann in 1610. Much greater antiquity has been accorded the operation, but apparently without sufficient data. The section is indicated when delivery by the natural passage is impossible, or of extreme danger to mother and child. This may be caused by deformity of the pelvis, intro-pelvic growths, or advanced maligunant disease of the cervix. For many years the mortality, 80 per cent. and over, which attended the Cæsarean operation, led to its practical abandonment, and we have to thank asepsis and Sänger for its present splendid showing. The former, as through it the danger of opening the abdominal cavity has been reduced to a practical no per cent.; and the latter for teaching us how to do the operation, and for dispelling the belief that, owing to the contraction and relaxation of the organ, suturing the uterine wound was not to be thought of.

Much has been written as to time of election, whether

we should wait until the pains begin, and also how much dilatation should be present, or whether we should operate at our convenience any time during the last days of pregnancy. Dr. H. C. Coe believes that the best time to operate is before labor has begun, and his opinion is strengthened by that of Dr. Robert P. Harris. Personally, I can see no object in waiting, and believe that results will be better if we thoroughly prepare the patient for operation, and then operate at our convenience. The argument that we may have a dangerous hemorrhage in cases where labor has not begun, is, I think, false; and one of the strongest proofs to the contrary is to be found in cases where, for one reason or another, the uterus is emptied during pregnancy but before the advent of labor. There are hundreds of such cases; and I have never yet heard of one where the organ did not contract, and of very few where hemorrhage, to any alarming extent, was present. The other argument against the operation of election was that the cervix, being undilated, would not permit free drainage. I believe this to be also a mistake. The cervical canal is always open, and is usually, during the last few days of pregnancy, so soft and dilatable always with multipara that the point of the finger can be introduced through it. This certainly gives sufficient outlet for all fluids, and moreover, a strip of gauze can be pushed from the uterine cavity down through the cervix into the vagina, giving all the needed drainage.

One other point, about which much has been written, is whether the uterus should be opened outside or inside the abdominal cavity. Both methods have warm supporters. I think, however, that the concensus of opinion is that it should be opened outside, Dr. H. A. Kelley to the contrary. Many cases where the uterus has been opened inside have later, on account of hemorrhage, necessitated the removal of the organ to the outside.

The cleanliness of the abdominal cavity is much better cared for when the uterus is outside; in fact, it need not be in the slightest degree soiled. The patient should, if possible, enter the hospital several days before the operation. The total amount of urine passed in twenty-four hours should be noted, and a careful examination of the secretion made. If there is any diminution in the amount, she should be encouraged to drink as much water as possible, and should have some mild diuretic. The skin must be in good condition, and hot baths are to be recommended. Her bowels must receive careful attention, and the rectum should be emptied by enema the day before the operation. The abdomen is to be scrubbed with green soap and peroxide of hydrogen, to be covered with a soap poultice for two or three hours, to be followed by a corrosive one which remains in position until the time for operating. The vagina is to be scrubbed with soap, and washed out with peroxide of hydrogen and corrosive sublimate, and lastly packed lightly with gauze soaked in peroxide. The bladder should be emptied just before the operation. Four assistants are needed; one to etherize, one to handle instruments and sponges, one to hold the uterus, and one to take care of the baby. The instruments are to be sterilized, and the assistants' hands and arms treated as in preparing for any laparotomy.

The incision is in the linea alba, and should be long enough to admit of easily taking the uterus outside. Hot sterilized towels are placed around the organ, and, if possible, the placental site determined; if it cannot be, an incision should be made through the uterine wall, in the median line, just below the top of the fundus, and extend down for about three and a half inches. A rubber ligature is placed lightly round the uterus at the cervical junction, not to be used save in case of grave hemorrhage. One assistant places both hands around the uterus, and in this way controls hemorrhage. If the incision exposes the placenta, it should be rapidly separated, and the child removed by grasping it around the neck, and given to an assistant.

The uterus is now freed from any remnants of placenta and membrane. Deep sutures are introduced about half an inch from the wound, and going down to the mucous lining of the organ, but not through it, and between these superficial sutures unite peritoneum to peritoneum. The number of sutures will depend upon the length of the incision, and will vary from three or four to eight. The material best suited for this purpose is braided silk, and should be of a size sufficient to insure against breaking. The abdominal wound is to be closed with silk or silkworm-gut; ergotine (five to ten miuims) is given subcutaneously, and the patient placed in bed. There is usually very little nausea following the operation, and in many cases the mother is able to nurse her baby.

Before reporting the case upon which I operated I wish to speak of the statistics of the operation. The result of Sänger's operations from 1880 to 1888 showed a mortality of 17.9 per cent. A report comes from Leipsic of 38 cases with three deaths, or eight per cent. I have collected 40 cases, operated upon in the United States since 1888, and of these nine died, a mortality of 22½ per cent. Of the nine deaths one case was operated upon without any antiseptic precautions; one had been in labor six days, and had had forceps and version tried; another had advanced malignant disease, and was dying at the time of operation; still another had been in labor two days, and had had forceps and version. This is true of a fifth, and the sixth death was in a case where labor had lasted five days and where the woman was septic. These cases should not properly be counted. If we omit them, we have three deaths in 34 cases, or a death-rate of between eight and nine per cent. It is also interesting to note that all cases operated upon in hospitals recovered, save one, and this was the case of advanced malignant disease. I think we can then assume that in all properly selected cases the mortality is not greater than nine per cent., and that in cases operated upon at the time of election, in hospitals, the mortality will be very much below nine per cent.

We then have Cæsarean section with a mortality of nine per cent., craniotomy with a mortality of five per cent., and induced labor with a mortality of five per cent.; in other words, Cæsarean section is, taking all cases, nearly twice as dangerous for the mother as craniotomy or induced labor. Undertaken in proper surroundings and by skilled operators, I doubt very much whether the mortality is greater, and the fetal mortality is wonderfully less.

It is a pity that statistics are so disappointing. Men prove whatever they wish, and in collecting statistics take many cases which should be omitted; for instance, if it is wished to prove that craniotomy or induced labor, is much safer than Cæsarean section, we have but to include all the cases of which I have spoken as unfit for the operation, our mortality immediately rises and the proof we wish is forthcoming.

I shall end this paper by reporting a case which I had the pleasure of operating upon in July, 1894.

E. F., born in England, thirty years old, of slight build, weight about one hundred pounds, entered the

[1] ...ad, by invitation, before the Obstetrical Society of Boston, De... 8, 1894.

we should wait until the pains begin, and also how much dilatation should be present, or whether we should operate at our convenience any time during the last days of pregnancy. Dr. H. C. Coe believes that the best time to operate is before labor has begun and

be, an incision should be made through the uterine wall, in the median line, just below the top of the fundus, and extend down for about three and a half inches. A rubber ligature is placed lightly round the uterus at the cervical junction, not to be need save in case of

if possible, the placental site determined; if it cannot

spoken as dumb for the operation, our mortality immediately rises and the proof we wish is forthcoming.

I shall end this paper by reporting a case which I had the pleasure of operating upon in July, 1894.

E. F., born in England, thirty years old, of slight build, weight about one hundred pounds, entered the Boston Lying-in Hospital on the 10th of July, 1894. She was a patient of Dr. George G. Sears, and was referred by him to the hospital. She was pregnant for the third time. Her first pregnancy was terminated by craniotomy, which was followed by sepsis, and she made a very slow recovery. The second was terminated by a very difficult version, subsequent to high forceps, by Dr. Edward Reynolds. The result in both cases was a dead child. Her pelvis was carefully measured by Dr. William L. Richardson, Dr. Charles M. Green and myself with the following results: spines 9 in., crests 10 in., trochanters 10⅞ in., the true conjugates 2⅝ in. The conjugate was apparently less than at the preceding delivery. The reason for this has not been determined. It must be stated here that she came to the hospital two months before the operation, seeking an induced labor, but was advised against it by Dr. William L. Richardson, as the danger was considered about equal to that of Cæsarean section, and she was very anxious to have a living child.

I shall make no comments upon the pelvis, save to say that it was too small to allow of but two operations, Cæsarean section and craniotomy. She was prepared for operation by the method already spoken of, and at 11.15 A.M., Sunday morning, July 15, 1894, she was given ether. She was on the table at 11.30. Drs. E. Reynolds, C. W. Townsend, J. W. Bartol, and Harlow assisted, and Drs. Richardson and Green were present. First cut in the abdominal wall 11.33, abdominal cavity opened 11.34. Uterus delivered from abdominal cavity 11.35½. Ligature round neck of uterus 11.36½. Uterus opened 11.38½. Placenta delivered 11.38 and 45 seconds. Baby delivered 11.38 and 55 seconds. Membranes delivered 11.39 and 20 seconds. Sutures begun in uterus 11.42, finished at 12.04. Sutures begun in abdominal wall 12.07, finished 12.19. Patient in bed 12.35.

There was no bleeding from the abdominal incision. Thickness of abdominal wall was about one-half inch. The bleeding from the uterus was very slight after the first gush, which was apparently merely the blood held in the organ. After the sutures were in position there was no bleeding. The abdominal cavity was not washed out, and the organ was merely replaced after suturing and the abdominal walls united. A subcutaneous injection of ergotine was given. The patient had in the evening an enema of bromide of potash. She was for a day or two more or less hysterical, was given bromide and champagne. The baby was nursed from the beginning, and gained steadily in weight. The mother was up in three weeks and left the hospital in four weeks. Her temperature chart is uninteresting. There was a slight rise during the first forty-eight hours, to be followed by a practically normal chart. Her pulse was never above 100. I saw her a short time ago. She was well, and had a remarkably healthy and fine son. The baby's initial weight was eight pounds.

I am indebted to Dr. Courtney for preparing the table of cases.

---

IN Toronto, children suffering from phthisis are forbidden attending public schools on the ground that they have a contagious disease.

## SYMPHYSEOTOMY.[1]

BY JAMES M. JACKSON, M.D.

NATURE has made a wise provision in certain of the lower animals, notably the guinea-pig, by which the symphysis separates sufficiently, just before parturition, to permit of easy transit of the fetus through the pelvis.

The operation which we are about to discuss is then an imitation of one of Nature's provisions. In these days an imitation is often quite as good as the original; but whether it will prove to be so in this case remains to be seen.

Symphyseotomy was first performed by Sigault, in Paris, in 1774. The mother and child both survived. This good result naturally enough lead many operators, especially amongst the Italians, to attempt the operation. The subsequent results were so bad and the mortality so great that it was finally abandoned, to be revived in 1866 by Morisani and Novi of Naples, with some degree of success. Three years ago the operation made its exit again from Italy and was taken up by Zweifel, Freund and Pinard. These men attempt to show that the operation is a practical and safe one under certain conditions, and we now find reports of cases in almost every obstetrical journal of to-day.

Sufficient time has not elapsed since the revival of the operation in 1890 and 1891 for us to form an honest estimate of the ultimate result, but enough cases have been reported to convince one that it is in reality a very serious operation.

At first glance it seems a very simple and easy procedure, which may be done in any household; but after following a case through from the operating-room to the pathological institute one may be excused, I think, for changing his opinion.

There are two methods of operating, the subcutaneous and the open; but as the time is limited I will describe the one in general use; the open method being by all odds the best, inasmuch as it gives the operator a chance to watch the separation of the symphysis and also to tie bleeding-points. The operation is never done until the os uteri is nearly or fully dilated and until high forceps have been attempted, — never after attempt at version.

Owing to the great liability to sepsis, the utmost care must be taken in rendering the lower part of the abdominal wall and vagina as aseptic as possible. An incision is made over the symphysis, extending upwards far enough to permit the operator to insert a finger back of the symphysis. Short lateral incisions are made at the lower end of the wound, and the fascia freed from its attachment to the pubes. The urethra is held to one side by inserting a stiff catheter. Then with a blunt-pointed, slightly-curved bistoury the symphysis is divided by cutting downward and backward. The sub-pubic ligament must also be divided in order to get sufficient separation. The pubic bones then spread apart a varying distance, but should not be allowed to separate more than eight centimetres, lest the sacro-iliac synchondrosis be ruptured. Up to eight centimetres there is little or no danger, as the articulation between ilium and sacrum is now known to be a true joint capable of slight movement. The head sinks at once into the pelvis.

Another great danger at this point is hemorrhage

[1] Read, by invitation, before the Obstetrical Society of Boston, December 8, 1894.

from the prevesical space thus opened. Vessels here cannot be tied and deep stitches do but little good, so that there is nothing left to do but pack with gauze. If this is not sufficient counter-pressure may be made by packing the vagina.

We may wait for a spontaneous delivery or apply forceps and deliver at once. Zweifel recommends waiting even twenty-four hours, if necessary, provided the fetal heart-sounds are good. A spontaneous delivery is of advantage because there is likely to be less damage done than by artificial delivery. Out of 44 cases which Harris cites, there were only eight spontaneous deliveries; and in 12 by Zweifel, only two. If after a reasonable time has elapsed without advance of head, or if the fetal heart-sounds give warning of danger, forceps should be applied. During the delivery the pelvis should be held by assistants lest too great a separation of symphysis takes place.

Delivery is usually easy, owing to the quite considerable increase in the diameters of the pelvis; but it is also very easy to wound the vagina at this stage, and herein lies one great objection to the operation. Several cases have been reported, and I have myself seen one case at autopsy, where the anterior wall was so torn that the finger could be passed from above the symphysis through into the vagina. The urethra in this case was also ruptured. Further, the sacro-iliac synchondrosis may be so stretched that a rupture of the capsule occurs, sometimes with direful results. In a pelvis which I once saw there was a large blood-clot in each joint, and also considerable pus, the woman having died of septicemia.

After delivery the symphysis is forced together, and may be held in place either by strips of adhesive plaster across the pelvis, or by suturing the pubic bones. Zweifel drills holes in each side of the symphysis and holds the ends together with catgut. With this a firm bandage should be worn. The prevesical space is always drained for one or two days.

The after-treatment consists in keeping the woman quiet in bed for three weeks with knees tied together. She is then allowed to get up if union of the symphysis has taken place. For six months she is not allowed to do any heavy work or straining. Each case must, of course, be treated *per se*, for there are cases in which the union is greatly delayed.

It seems illogical to think that symphyses should heal in so short a time, but, as a fact, most of them do, at least that is what is claimed. I know of a case in Vienna where the woman was in bed the greater part of six months, and even then could walk only with the greatest difficulty on account of failure of union in the symphysis and great laxity of the sacro-iliac joints. In another case, the woman waddled in walking, which was also due to partial non-union, though she was able to get about without much difficulty.

I wish here to cite a case reported by Garrigues. The operation was a success, and everything went well. At the end of a month the patient went home, apparently well. The symphysis at that time had united except at the lower end, which would just admit the finger-tip. At the end of three and a half months the patient returned, with waddling gait and pain in all three joints of the pelvis when walking. Examination showed that the lower end of the symphysis had separated half an inch.

Another source of danger, which I may mention here, is from cystitis or even suprapubic fistula of the bladder, due to a pinching of the bladder wall between the ends of the symphysis.

Garrigues says that by division of the symphysis the distance from the middle of the promontory to the ends of the pubic bones increases 14 millimetres, and during birth an additional gain of 6 to 8 millimetres is made, or 20 to 22 millimetres in all, and that the increase in other diameters may amount to as much as 35 millimetres. Döderlein estimates that by a separation of the pubic bones of 6 centimetres a superior strait of 105 square centimetres would be increased to 155 square centimetres. The distinct advantage of such a gain in pelvic measurements needs no comment.

The disadvantages, as already noted, are as follows:

(1) Rupture of the sacra-iliac joints. Now that we know that a separation of more than eight centimetres of the symphysis is liable to rupture the capsule of these joints, such an accident need hardly occur.

(2) Rupture of soft parts of vagina and urethra. This is not a rare complication, and to my mind is a strong point against the operation.

(3) The danger of non-union of the symphysis. Sandberg, in his article on symphyseotomy in the *American Journal of Obstetrics*, for February, 1894, says: "Faulty union of pubic bones, resulting in impaired locomotion was one of the great objections to the operation in its early period. Since its revival and especially during the last six or seven years, failures in this respect are almost unheard of, whether the operator applies bone sutures or only keeps the divided bones in apposition by a firm bandage." In my very limited acquaintance with the operation I know of two cases of non-union. I will admit, however, that such cases are, as he says, "almost unheard of." Zweifel reports three cases of waddling gait out of 23 symphyseotomies; Fritch four out of four; Graudin one out of four; and Garrigues one out of two. In all of these 33 cases, nine had disturbed locomotion.

It has occurred to me that there is an analogy to be drawn between the healing of the symphysis after this operation and the healing of a compound fracture of the patella. We know that in the case of the latter 6.6 months on the average are necessary for a union (according to Dr. J. G. Mumford's statistics) which in most cases is by cartilage, and that about half these cases break down or stretch afterwards. If the analogy is correct is it not just to infer that a like result may take place in the symphysis? The case of Garrigues already cited, seems to be a good illustration of this point.

(4) The length of time required in convalescence, which may be said to be quite as long as in Cæsarean section. Three weeks in bed, getting up gradually according to the amount of union in the symphysis. No hard work for six months to a year.

(5) The great liability to sepsis which is shown in cases where there has been a bad laceration of the vagina. I judge merely from autopsies and post-mortem specimens which I have seen and from a few reported cases, all of which were under the care of good operators.

Lastly, the rate of mortality. It has been placed at 10 per cent.; but this I feel is entirely too high. It ought not to exceed two or three per cent., with our recent methods and with greater care in selecting cases. It is obviously unfair to count cases that have been tampered with by meddling midwives and uncleau doctors before the operation, or cases in which labor

has been going on for one or two days until the patient is in a low condition. It is on this account that the mortality in America is so high, according to Garrigues, namely, 15.39 per cent. for mothers and 30.77 per cent. for children in 26 cases.

We must admit that as yet operators are inexperienced, and the mortality is high on that account. Zweifel, in his 14 reported cases, has not lost a mother, though he has lost two children, which may give us considerable hope of the future success of the operation.

Indications. Symphyseotomy finds its proper field in contracted pelves, both flattened and generally contracted, and in certain impacted, faulty presentations of the vertex.

The following limits should be carefully observed: in flattened pelves, with conjugate vera of from 6.5 to 8.5 centimetres, and in generally contracted pelves from 7.5 to 9.5 centimetres. In pelves below these measurements Cæsarian section is indicated, forceps or version above. The operation should not be done until high forceps has been tried; nor is it indicated if the woman is in poor condition or the child dead.

Symphyseotomy comes, then, as a direct competitor of Cæsarean section, craniotomy and premature deliveries. The feeling here in Boston is so strong in favor of saving the mother always, even at the expense of the child, that it will be a long time before either Cæsarean section or symphyseotomy will be generally practised; for even in the most skilful hands there is considerable danger in these operations, while in craniotomy or premature delivery the mortality ought to be nearly nothing. Again, the same difficulty arises with symphyseotomy as with Cæsarean section, namely, the length of time necessary for complete recovery, which is of considerable moment amongst the poorer classes. Enthusiasts in the new operation claim that it is no longer justifiable to elect deliberately embryotomy in place of Cæsarean section and symphyseotomy, but until they can show a lower rate of mortality; both maternal and fetal, and better after-effects, the conservative American will continue to practise as heretofore. There has been some controversy over the question as to whether the operation should ever be attempted outside a clinic. So many assistants are required and such careful nursing afterwards that it makes the operation impracticable except in clinics and rich families.

In closing, I may say that the opportunities of this operation are enormous, provided certain present objections can be removed. I do not agree with many who claim that the great mortality is sufficient to condemn the operation, for in skilful hands the death-rate ought not to exceed two or three per cent. In 100 cases by Zweifel, Pinard and the Italians the mortality was only two per cent., which makes a very good showing.

My personal objections to the operation are rather on account of the lacerations which may occur during delivery and the bad after-effects; and until we can be assured of better results in these respects the operation is *not*, I hold, a success, for of what advantage is it to save a child and perhaps cripple the mother for years? Then, and not till then, will Dr. Garrigues' remarks be pertinent, in which he says: "Craniotomy on the living child is a repulsive operation that has met with just condemnation from many sides. As long as the only alternative was Cæsarean section I did not hesitate to sacrifice the child in order to save the mother; but since in symphyseotomy we have got an operation almost without danger to mother and with moderate danger to child, I do not think that any man should be compelled to, or justified in, deliberately murdering the child, provided the necessary conditions for a successful symphyseotomy can be brought about. . . . If we take the most skilful operators, the mortality of symphyseotomy is practically nothing, against eight per cent. in Cæsarean section. One must, therefore, be a fanatic worshipper of the latter operation in order to think of performing it when the former is practicable.

## Clinical Department.

### A CASE OF PERSISTENT HEMATURIA.

BY CHARLES F. DENNY, M.D., ST. PAUL, MINN.

My only apology for offering this case for publication is its chronicity, and its ultimate cure without recourse to operative methods. It shows that by perseverance in treatment we sometimes may succeed where we least expect, without radical measures. On November 27, 1893, I was consulted by a gentleman, who gave the following account of himself:

Mr. J. K. M., a Scotchman, married, age thirty-nine years. Both parents living in good health. Grandparents all died old. One sister died of scarlet fever. One brother died of phthisis, induced by a cold; no other cases in the family. At ten years of age, he was seriously sick with a fever, presumably of a typhoid type. At twenty-nine years of age, he had a mild case of gonorrhea, and in the summer of 1891 he had a diarrheal difficulty which lasted from four to six weeks.

During September, 1892, while on a hunting trip, he got chilled to the extent, that he claims his teeth chattered, and soon after this he noticed his urine was dark colored, as though mixed with blood. From that time to the present his urine was never free from its dark color. His habits in regard to liquors were correct, as he never abused or made a steady use of them. Tobacco he does not use in any form.

His general health is excellent. He suffers no pain or discomfort whatever in his bladder or genitals. Long standing or overwork of any kind will produce a darker urine. For the relief of his condition he consulted several physicians, among the number two of the most distinguished regular practitioners in this vicinity. From both he received the information that he had bloody urine. From both he received internal treatment. From neither did he receive any local treatment. From the one who treated him the longest he received but little encouragement as to cure. When he presented himself to me it was not with a great deal of enthusiasm as to permanent results. Examination showed a large knotty varicocele on the left side, the vessels standing well out on the scrotal surface, and the cord easily felt beneath. On calling his attention to this, he said "that it had existed since a horse-back ride when fifteen years old, and was aggravated by a blow received, four years prior to his present trouble, on his privates, while in a saw-mill." The varicocele, large as it was, gave him no discomfort whatever and that fact was accounted for by his use of a suspensory bandage.

Nothing was noted in reference to the penis save it was long, and pendulous. The meatus was free from any discharge, and easily admitted a 19 A. (29 F.) sound. On passing a full-sized Otis bulb slight catching was felt at one inch, and at two and three-quarters inches from the meatus. These slight strictures evidently resulted from his gonorrhea, and offered no obstruction to the passage of the 19 A. sound. A No. 11 A. bougie at five and a half inches from the meatus seemed to meet more resistance than normal on pushing it on into the bladder, but this was probably a simple spasmodic contraction, as the No. 19 sound ran easily into the bladder. Rectal examination detected no prostatic or vesicular hypertrophy; not even tenderness on pressure was noted.

On applying the two-beaker test (Thompson's test), both catches of urine were dark-mahogany color. The urine when drawn by a catheter directly from the bladder was the same color. He was requested to bring a specimen of the morning urine the next day, which he did. Its specific gravity was 1.028; its reaction was acid; and it rapidly precipitated, leaving a heavy, dark red-brown sediment in the glass. Placed under the microscope this sediment showed free blood-corpuscles in profusion. A few bladder cells and fibrinous shreds. Acetic acid developed a few round nucleated cells. The amount of urine was up to the daily normal average.

I explained to him that I believed he had a small villous growth in the bladder which was the cause of his hematuria, and that local treatment might be of curative action, and should be tried before any operative measures were taken.

Before taking the case it was distinctly understood that he was to be treated until it was clearly demonstrated he could not recover without an operation. It was due to his willingness to keep this compact that the ultimate result was so satisfactory. He had previously been treated internally with ergot and gallic acid. My first endeavor was to see how much internal medication would affect the hemorrhage. He was given large doses of gallic acid, ergot, tr. ferri chloridi, ol. erigeron, and others, singly and in combination. Since Jamaica rum had been successfully given in a case of hematuria, he was dosed with that beverage. Fl. ext. pichi was given a trial. But beyond the most trifling effect as to color, nothing resulted. Everything was fairly and thoroughly used.

December 14, 1893. The bladder was first washed out, through a catheter fitted to a Hosmer tube, with warm water from an irrigating bottle until it ran clear, then a weak solution of permanganate of potassium, two grains to one pint, was allowed to run in. The last six ounces were retained in the bladder for several minutes, the catheter being withdrawn. He then passed the greater part himself, except about an ounce which was allowed to remain.

Shortly after this the urine was somewhat clearer, though still dark tinted. The microscope showed less blood but rather more bladder and prostatic epithelium in stringy masses. The permanganate solution was used in increasing strengths up to two to three grains to one ounce. But beyond slight improvement no material change was noted. The bladder was exceedingly tolerant, and very distensible. He could with ease retain large amounts of urine.

January 16, 1894. Hot water was used, gradually increasing the temperature up to 110° F. and at times even warmer. During this period a few medicated injections of alumnol, tannic acid, and Lloyd's hydrastis were used, always after the hot irrigation. These hot injections were allowed to thoroughly distend the bladder, and were retained for several minutes, the process being repeated until about a quart of the water was used. This was continued every other day for several weeks, with improvement. On Sundays, when resting, the urine was much clearer, still never transparent or free from a dirty-white tinge.

March 27, 1894. Dr. G. A. Renz, of St. Paul, examined the urine carefully for me, for bacilli, with negative results, so as to exclude tubercular disease. March 19th, prior to the examination for bacilli, silver-nitrate solutions were commenced, after thoroughly cleansing the bladder with warm water. Two ounces of half-grain to one-ounce strength were injected, and held for a short time before withdrawing. This was done every two or three days, slowly increasing the strength until six grains to one ounce was reached.

These injections never gave any trouble save a slight desire to urinate a short time after treatment. His tolerance was far above the average in this respect. The urine voided several hours after injection was darker and heavier. Specimens he brought and passed for me at this time showed a dark, whitish sediment, which under the microscope disclosed less blood and decidedly more cells and fibrinous string. As treatment progressed, this sediment became thinner, until a point was reached where it seemed to reach a standstill.

On Saturday, April 7th, I gave him an injection of silver nitrate (five grains to the ounce), and the following morning his urine was very dark and thick, and then became lighter the rest of the day. On the next day, to his surprise, his first passage of urine was clear and transparent. On April 10th he voided, in my presence, an apparently normal urine. This, on standing, settled to a light, whitish cloud, no more than is often seen in normal specimens, and the microscope showed a few scattering blood discs and a trace of epithelium.

On May 7th no blood was found. Again, on July 30th, an examination failed to find blood, and no more epithelial *débris* than normal. A few calcic-oxalate crystals and a small mucous string were the only results.

Up to the present date of writing, December, 1894, no relapse has occurred, and he considers himself cured.

In considering this case it is to be regretted that a cystoscopic examination of the bladder could not have been had, and the villous growth actually demonstrated; but a Leiters instrument was not at my command. Had it been used, I believe the growth would have been found at the base in the vicinity of the trigone.

These cases are always troublesome, and slow in their course, oftentimes giving rise to no symptoms save hemorrhage. They should be carefully studied.

After a considerable experience of genito-urinary disorders during the past thirteen years I can testify to the fact that careful study and perseverance are the essentials of success in this branch of medicine. "Make haste slowly," is only too true, and should be firmly fixed in the mind of all who assume such work. To simply say "you have blood in the urine" is small consolation to a patient. You must seek its source, from what part of the urinary tract it arises, its cause

if possible, and then direct your efforts towards its cure. Try one thing at a time thoroughly, and shelve it when it proves of no use. In no class of cases should the tolerance of a patient's bladder be more fully considered. This fact should be ascertained by gradual increase in strength of solutions used, and any irritation that does not readily subside should be avoided.

My experience has taught me that of all chemicals used in genito-urinary work silver nitrate is the most useful. It is an agent of great good, or great evil, as its proper or improper use will quickly demonstrate. No agent is so much abused in its use as this, and no other agent can be made to do so satisfactory work with proper care.

One of the first essentials in bladder applications of all kinds is thorough cleansing. It matters little whether mild carbolic or boric-acid solutions or warm water alone are used, the organ must be washed out until the washings run clear, in order that the active medication may have full play in an organ as free from foreign matter as possible. With silver solutions mild strengths should be first used, half a grain to the ounce, from two to four ounces being injected at once, and retained a short time and then withdrawn. The time of retention may be slowly increased with benefit from time to time. This is purely a matter of judgment, to be decided wholly by the tolerance of the patient. The solution is slowly increased in strength up to ten grains to the ounce in some cases. Some cases are very intolerant of strong solutions, hence the necessity for slowly feeling your way grain by grain. If more than ordinary reaction occurs, they should not be continued. As a rule, silver injections should not be used oftener than every three to seven days.

The subject of bladder growths is so fully considered in the many text-books, that it is not my purpose in a clinical picture of this kind to enter into any extended discussion. But I do wish to emphasize the fact that many cases are brought to the operating-table which more perseverance in local treatment might subdue. And while I am fully aware of the prejudice that exists in the minds of many against the stronger solutions of silver, and while at the same time no one more than myself would shun their careless abuse, I must say, that with due care no harm, much good, and many cures will result where otherwise surgical operation would be required. I do not decry operating in proper cases, many of which occur.

## MULTILOCULAR CYST OF THE OVARY; DOUBLE OVARIOTOMY; RECOVERY.[1]

BY JOHN S. PHELPS, A.M., M.D.

Mrs. M., age twenty-five, born in Ireland. Seen for the first time in August, 1894, with reference to present trouble. Owing to her poor physical condition, interference was postponed until her return from the summer hospital where she was to go with her sick baby, in hopes that the rest and change might build up her own strength as well as that of her child. She presented herself in September markedly improved.

She never was rugged, but always had enjoyed good health. She was married in April, 1893, and gave birth to a child in February, 1894. She first noticed a swelling in her lower abdomen one year before marriage, which swelling had increased in size slowly up to the present time. In the hands of different physicians she had been tapped on three occasions. The first time in March last, nearly two years after the appearance of the swelling, eighteen quarts of "muddy" fluid were withdrawn. Five weeks later thirteen quarts were taken away; and in May last she was relieved of five quarts, according to her statements.

She had no gastric disturbances; never any marked bladder symptoms. Catamenia normal since childbed. No metrorrhagia, general health had grown steadily worse in the last six months with loss of flesh and nervous depression.

Physical examination showed her to be a woman of slight frame and fairly well nourished. Heart and lungs were negative. Urine negative. The abdomen was markedly distended and appeared larger than that of a gravid uterus at full term; dull on percussion. The tumor apparently was movable and very tense. She never had had any symptoms of local peritonitis.

Vaginal examination showed uterus to be free from adhesions, two and a half inches deep and somewhat anteflexed. There was moderate tenderness in the regions of the ovaries.

The operation was performed October 5, 1894, at St. Margaret's Hospital, Dr. Farrar Cobb assisting. An incision two inches long, over the most prominent part of the tumor, in the median line, showed it to be firmly adherent to the parietal peritoneum. The incision was then enlarged to three and a half inches upwards, opening the peritoneal cavity. Inserting the hand, the extensive adhesions to the abdominal wall were with difficulty finally separated. The tumor was then aspirated after being walled off, and several quarts of gelatinous fluid welled out through the lacerated opening made by the large canula. Inserting the hand into this cyst allowed the puncture of a second cyst, and the escape of a large quantity of a clear yellow serous fluid with partial collapse of the tumor enabling its delivery. Adhesions to omentum and bladder and intestines were ligated and cut away.

The tumor had a long pedicle about one and a half inches in width arising from the right tube, with obliteration of the ovary. This pedicle was clamped, doubly ligated with braided silk, and cut away. No bleeding. Further examination showed the left ovary cystic and enlarged to the size of an orange. This was likewise removed. The abdominal cavity was thoroughly dried by dry gauze sponging, and the wound of incision sewed up with interrupted silkworm-gut sutures. The operation lasted one hour, leaving the patient in excellent condition.

The convalescence was uneventful, the pulse and temperature remaining practically normal. Some abdominal pain developed on the second day, which was relieved by the escape of gas through a rectal tube, and later by an enema combined with the administration of salts.

Examination of the wound on the seventh day showed perfect coaptation and union, and the stitches were removed. Patient went home on the sixteenth day wearing a firm abdominal support.

The weight of the tumor, estimated from the weight of the patient before and after operation was about twenty-five pounds. The extensive adhesions caused

[1] Read before the Surgical Section of the Massachusetts Medical Society, January 2, 1895.

by repeated aspirations impeded the progress of the operation.

The girth of the abdomen at navel before operation and after was thirty-four and a quarter and twenty-seven inches respectively.

Since operation the patient, under moderate tonic treatment, has gained rapidly in strength and bodily weight, as is not unusual in this class of cases.

Specimens shown.

## Medical Progress.

### RECENT PROGRESS IN LARYNGOLOGY.

BY A. COOLIDGE, JR., M.D.

#### FOLLICULAR TONSILLITIS.

A PAPER by Dr. Norris Wolfenden on "The Nature of So-called Follicular Tonsillitis and its Relation to Infectious Disorders,"[1] describes recent progress in the study of this disease, with special reference to its bacteriology. The author believes that the time is not far distant when we shall classify the inflammatory condition of the tonsils and throat upon a bacteriological and not a clinical basis. He describes briefly four varieties, omitting all cases in which the bacillus of diphtheria plays a part, under the head of staphylococcal, streptococcal, pneumococcal, and Roux and Yersin coccal angina. In all of these forms there may be throat symptoms which resemble diphtheria. "Follicular" tonsillitis is not really follicular at all; it is an acute cryptic infection due to one of these forms of cocci. Its contagiousness appears established in some cases, but is generally not very easily traced. It never appears to attack large masses of people simultaneously, although a number of persons living under the same roof or in the same conditions are frequently affected at the same time, suggesting insanitary surroundings as a common cause. The pathological enlargements of the tonsils, in which a chronic process of catarrh is present in the crypts, form not only the best culture media for a large number of micro-organisms but give their products an opportunity to invade the system. Clinical appearances alone often allow so little ground for diagnosis of simple tonsillitis from diphtheria that in the absence of bacteriological diagnosis it is wise to isolate such patients from the first.

#### SURGICAL TREATMENT OF TUBERCULAR LARYNGITIS.

At the recent International Medical Congress this subject was taken up at length by two or three writers and discussed by members of the section. The result on the whole tends to show that there still exists a very wide difference of opinion as to the amount to be hoped for by the more active methods of dealing with this disease. An exhaustive paper by Heryng contains a long list of conclusions generally favorable to surgical interference. He has observed spontaneous healing in fourteen cases out of three thousand, all of them simple cases. The best chances for recovery are where the disease shows itself in the form of infiltration on the posterior wall of the larynx and in which the epiglottis and cartilages of Santorini are not affected, and where the lung affection is slight. For relief of dysphagia, or difficulty in breathing, operations may be necessary from which there is no hope of curing the disease. The healing of deep ulcers of the larynx resting on inflammatory infiltrations is effected quickest by scraping, or removal of the tubercular tissue. Lactic acid is indicated in superficial, circumscribed ulcers of a dirty character, covered by spongy granulous tissue on the vocal cords, false cords and posterior wall of the larynx, and is useless in most cases of large, hard and diffuse infiltrations. Surgical treatment is contraindicated in advanced disease of the lungs and in all cachectic conditions, in diffuse miliary tubercle of the larynx, in severe stenosis, and in patients exhibiting fear and nervous excitability. Surgical treatment demands great perseverance and patience, well-made sharp instruments, and careful after-treatment for a long time. The galvano-caustic treatment of hard tumors of the false cords, of sclerotic infiltrations of the epiglottis and formations of granulations in the ventricles is often of use. Serious bleeding is rare; it can be stopped by an application of a mixture of lactic acid and sesquichloride of iron. In rare cases a dissemination of the tubercle has been observed after surgical interference. Recurrence takes place frequently at the place operated upon and may be explained in some cases by the imperfect performance of the operation.

The discussion on this paper and on one by Gouguenheim on the same subject brought out considerable difference of opinion. Sokolowski calls attention to the fact that cicatrization of laryngeal tuberculosis takes place when the general tuberculous process has a tendency to stop in its development, more or less independent of different therapeutic methods. Lactic acid, iodol, iodoform, menthol, parachlorphenol, as well as surgical treatment sometimes result in improvement, but results are more often negative. He was inclined to favor thyrotomy if any extensive surgical treatment was considered advisable. Egidi favored tracheotomy as a curative proceeding for the larynx. Several speakers had obtained good results from the local action of phenol sulphoricinate. From these different papers we may conclude that up to the present time we cannot expect to get more than temporary relief in cases of laryngeal phthisis except in very rare cases, and that no one form of treatment is applicable to the large number of appearances which tuberculosis may present in the larynx.

#### EMPYEMA OF THE ANTRUM.

Garel,[2] in a paper on this subject, comes to the conclusion that irrigation by the natural orifice is the most expeditious therapeutic method and the first that ought to be tried. It is useless to try to penetrate by the most dependent part, as statistics show no better results in these cases than in any cases perforated higher up. When an artificial opening is to be made, the inferior meatus gives better results than through the alveolar process, except in those cases where it is necessary to extract a foreign body from the cavity. Rebellious cases which have resisted all treatment by irrigation may require opening through the canine fossa and curetting as a last resort. As an irrigating fluid nothing gives better results than a solution of boric acid.

Dundas Grant[3] advocates perforation of the antrum, when this is necessary on account of empyema, through the inferior meatus. The advantages of this opening are, that it confines the discharge of pus to the nose,

[1] Journal of Laryngology, August.

[2] International Medical Congress.

[3] British Laryngological Association, October, 1894.

that it is easily performed by local anesthesia or by short general anesthesia, that the cavity is easily irrigated by the surgeon, and that it hastens recovery. Though not at the most dependent part, it is very near it, and generally sufficiently so. Its disadvantages are that it requires a certain amount of skill on the part of the operator, often requires his aid for subsequent irrigations, and that the opening tends to close rapidly. Krause's instrument, a slightly curved trocar, as sharp as possible, is introduced into the inferior meatus a distance of about one and a half inches. The point is then pushed upwards and backwards and very cautiously forced, with more or less of a crunching sound, through the outer wall of the meatus. The trocar is then withdrawn and the canula is pushed inwards and the cavity washed out with a warm solution of boracic acid. The subsequent washings are done by again introducing the canula, under cocaine, armed with a blunt obdurator in the place of the trocar.

### RECURRENT EPISTAXIS.

Roth,[4] in a paper treating of the various causes of recurrent nose-bleed, shows that the description of the most common cause deserves special attention from the general practitioner who frequently does not appreciate how easily it may be both temporarily and permanently stopped. An erosion or varix of the cartilaginous septum, generally but a short distance within the nose, is often the cause of frequent and annoying bleeding. It may be readily stopped by tamponing during the bleeding, and permanently by the application of the galvano-cautery, trichloracetic or chromic acid. The bleeding spot is often easily found by gentle friction with a probe. A pledget of cotton, moistened with cocaine, is laid against the surface until the bleeding stops, and an application of the cautery or caustic can then be readily made.

### REMOVAL OF ADENOID VEGETATIONS BY THE COLD SNARE.

Professor Chiari,[5] of Vienna, recommends this method of removing adenoids in cases where the nasal passages are straight enough to allow the introduction of the instrument. Both nasal passages are cocainized by cotton-wool swabs dipped in a twenty-per-cent. solution of cocaine. The snare, placed vertically, is then passed through the inferior meatus until it reaches the naso-pharynx; it is then turned horizontally, the wire passing underneath the vegetations, and elevated. By closing the snare the growths are readily removed in most cases. After repeating this process three or four times through both nostrils, the loop being closed in different parts of the naso-pharynx, the patient goes home, to return later for a subsequent operation if necessary. The hemorrhage is slight, and the after-effects generally nothing. With reasonable children no assistance is required; with unruly ones, the head is held firmly and the body wrapped in a sheet. The after-treatment consists in gargles and a wash of a mild solution of permanganate of potash. The second operation should not be undertaken until the nasal mucous membrane has recovered from all irritation. In most cases from one to three sittings are sufficient. Unless the nostrils are narrow this operation is done even on very young children. Chiari considers this method at least not inferior to others, and in many cases much more thorough. There is an almost absolute freedom from danger, since the snare introduced in this way can seize nothing except the vegetations. The bleeding is very slight and by cocaine can be made painless. Where septal spurs or other obstructions prevent the complete removal in this way, it is sometimes necessary to use Gottstein's curette, or cutting forceps.

[4] Wiener med. Presse, No. 23, 1893.
[5] International Medical Congress.

### BEDNARS APHTHÆ.

E. Fraënkel[6] describes this benign affection as found only in the new-born, and as always situated over two symmetrical parts of the hard palate. Examination shows that it begins with the entrance of bacteria under the epithelium, producing an elevation with a little serous exudation beneath and sometimes laceration of the mucous membrane. Careful cleaning is the best treatment.

### TUBERCULOSIS OF THE NOSE.

Strauss[7] has found tubercle bacilli in the nasal fossæ of several pupils and nurses in the hospital. In spite of this fact, local tuberculosis of the nose is comparatively rare. Chiari[8] has seen only six cases in about six thousand patients. Generally the ulcer first appears with granular edges, giving rise to bleeding and obstruction, but with no pain.

### SPONTANEOUS CURE OF PHARYNGEAL TUMORS.

D'Aguanno[9] reports a few cases in which new growths of the pharynx or naso-pharynx have disappeared without the aid of any method of treatment. That this takes place in the case of adenoid vegetations is well known, and certain new growths which though unsuspected may be syphilitic will disappear under iodide of potash; other benign tumors also not infrequently decrease in size or disappear without any very evident cause; but the author has collected a few cases in which sarcomata, apparently steadily advancing and threatening life, have taken on a retrograde growth, or even disappeared. This occurs especially in those tumors very rich in vessels. The retrogressive phase takes place most frequently through alterations in the walls and contents of the vessels; and in other cases the growth appears to be destroyed by some special parasitic infection, notably erysipelas.

### RHINOSCLEROMA.

Paewlowsky[10] describes the treatment of two cases of this disease by an extract of cultures of the rhinoscleroma bacillus. A glycerine extract was injected subcutaneously, and was followed, in the cases suffering from the disease, by a general and local reaction, the affected tissue becoming much reddened and swollen. Injections were continued every second day for six months and a year respectively, at the end of which periods the disease had made no progress. The author believes that the extract may be used as a diagnostic agent.

---

ONE of the curiosities of surgical therapeutics is the treatment of tubercular peritonitis by insufflations of air (H. Folet, *Revue de Chirurgie*). After removing serous fluid with an aspirator, the peritoneum is blown up like a bag, three or four litres of air being thrown in. The results are said to be good.

## Reports of Societies.

### THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

REGULAR Meeting, December 8, 1894, the President, DR. CHARLES M. GREEN, in the chair.

DR. J. M. JACKSON read, by invitation, a paper on

SYMPHYSEOTOMY.[1]

DR. GEORGE HAVEN read a paper on

CÆSAREAN SECTION.[2]

DR. A. D. SINCLAIR referred to the mobility of the symphysis in the lower animals resulting in easy parturition.

DR. H. F. VICKERY said he had twice induced labor prematurely at the eighth month in women who had previously lost children in difficult labor. In both the pelvis was of a masculine type with narrow arch. In both the infants lived.

DR. EDWARD REYNOLDS said that the operation of Cæsarean section was, with the modern methods, a very easy one, and not to be compared with many abdominal operations which are done every day. Some three years ago he looked up some forty cases of Cæsarean section that had been operated on early, under good conditions, and with no complications present, in which sero-serous sutures were used. Among these there was only one death and that from sepsis, and under these conditions he does not believe the operation is more dangerous than any abdominal operation.

As regards premature delivery, he thinks the mortality for the mother, if healthy, ought to be *nil;* but with the children the results are poor, as so many die.

The differences obtained in the measurements in Dr. Haven's case he believes were due to the fact that the vagina was dilated when the first measurements were taken, and was contracted by cicatricial adhesions in the second instance.

DR. F. B. HARRINGTON said he should think it would be best to perform the Cæsarean section under favorable circumstances rather than wait for the onset of labor. The operation does not impress him as being a very difficult one.

DR. W. L. BURRAGE said he saw at the New York Infant Asylum a symphyseotomy done by the open method where there was a separation of two and a half inches. It impressed him as an operation of considerable magnitude, with many unfortunate possibilities, and not to be undertaken lightly.

DR. J. B. SWIFT believed that Cæsarean section should be an operation of election as to time, this of course points to the importance of measuring the pelvis before labor.

DR. EDW. REYNOLDS said that the field for symphyseotomy was a narrow one. The operation had been done where the pelvis was normal and there was no need for it, also where the pelvis was too small and where Cæsarean section was alone to be considered. In cases where there is moderate narrowing of the pelvis, and where the labor has been tedious and forceps have been tried in vain and where the child is still living, here Cæsarean section is very fatal, but symphyseotomy has its proper field. When one man can report thirteen cases in one year with only one death, the operation is certainly worth consideration.

[1] See page 181 of the Journal.
[2] See page 179 of the Journal.

DR. G. HAVEN would prefer in case of election the Cæsarean operation. The mortality from both symphyseotomy and Cæsarean section ought to be nothing, but in symphyseotomy we have the great danger of chronic invalidism from the effect on the pelvis.

As to induced labor, there is certainly a mortality here, but it is due to the method. To use a catheter and let it stay in several days is very apt to cause sepsis, manual dilatation with immediate delivery should be done at the first.

DR. W. L. BURRAGE showed a sterilizer.

## Recent Literature.

*A Manual of Organic Materia Medica and Pharmacognosy.* An Introduction to the Study of the Vegetable Kingdom and the Vegetable and Animal Drugs, Comprising the Botanical and Physical Characteristics, Source, Constituents, and Pharmacopœial Preparations. With Chapters on Synthetic Organic Remedies, Insects Injurious to Drugs, and Pharmacal Botany. By LUCIUS E. SAYRE, Dean of the School of Pharmacy, Professor of Materia Medica and Pharmacy in the University of Kansas, etc. With 543 Illustrations, the majority of which are from original drawings. Pp. xx, 555; 8vo. Philadelphia: P. Blakiston, Son & Co. 1895.

This work is rather a new treatise than a revision of the author's earlier "Organic Materia Medica and Pharmacal Botany," which appeared in 1879.

The 624 drugs mentioned in this new work are classified according to physical characteristics and also according to their botanical relationship, but by a system of numbering, their place in either classification is at once apparent. The nomenclature and general character of the text conform to that of the last revision of the United States Pharmacopœia, unofficial drugs being distinguished, however, by a different type and setting of the article.

The 222 illustrations in Part I are, except those of the starches, taken mainly from Bentley's "Manual of Botany." Most of the remaining 320 illustrations in the work are new, and were prepared under the direction of C. E. McClung, Ph.G. (Kansas University 1892).

The preparation of the text and illustrations have been creditably done, and the work is one that students and teachers of materia medica and pharmacognosy will find very useful. B. F. D.

*A Treatise on the Diseases of the Ear.* By T. MARK HOVELL, F.R.C.S. Edin., M.R.C.S. Eng. London: J. & A. Churchill. Philadelphia: P. Blakiston, Son & Co.

Of the 697 pages of this book 81 are devoted to a description of the structure and functions of the ear, and the remainder to a consideration of the various diseases and their treatment; there are 122 excellent wood-cut illustrations in the text; and these together with the systematic arrangement of the subject-matter and the plan of beginning important paragraphs with headlines to attract the eye, make the book a convenient one for purposes of reference, while more careful reading shows that the author has not only brought to bear upon his subject the results of a valuable personal experience, but has taken into consideration, and used

for purposes of comparison, the work of other writers. An example of this is to be found in the chapter upon the mastoid operation, while, on the other hand, the question of middle-ear operations is dismissed in a few paragraphs.

The following remarks upon the removal of adenoid growths may be read with interest in view of the differences of opinion among rhinologists as to the method of treating this condition.

"Owing to the frequency with which this disease occurs, a large number of patients have to be operated upon at hospitals and on account of the time occupied by the administration of the anesthetics, there is a tendency among some surgeons to remove the growths without the patient being anesthetized. If the object aimed at was merely to re-establish nasal respiration, no great amount of harm would be done by adopting this course; but as the middle ear is very frequently affected, it is most important to remove the source of the naso-pharyngeal catarrh which usually co-exists. This end will not be gained if portions of growth are allowed to remain; and I am well aware that this usually occurs when the operation has been performed without the patient being anesthetized. At the present time, sufficient attention has not been paid to the ear complications associated with post-nasal growths by surgeons who do not make a special study of aural diseases; but it is to be hoped that they will soon awaken to the fact that the establishment of free nasal respiration should not be the only object for which the operation is performed.

"With regard to the choice of anesthetics, it is best in most cases to place the patient fairly under ether, and to keep up the anesthesia with chloroform whilst the actual operation is in progress. An exception must be made, however, when dealing with infants, and in their case chloroform or the A. C. E. mixture should be employed in preference to ether. Many surgeons prefer chloroform throughout for all cases; and, at first sight, this anesthetic appears to be specially indicated. But in addition to the greater safety of ether as a routine anesthetic, it is certainly far safer than chloroform in operations about the naso-pharynx, involving free hemorrhage. The deep and audible breathing under ether; the tendency to occasional coughing and swallowing which attends its administration; the remarkable manner in which the circulation holds out, when, as occasionally happens, respiration becomes temporarily interfered with during the operation; and the rapid and permanent cessation of hemorrhage after the anesthetic has been withdrawn, are all weighty reasons for selecting this agent. It is true that patients breathe more easily under chloroform, and hemorrhage may be less during the operation; but the noiseless manner in which breathing may become obstructed under chloroform; the rapidity with which the circulation runs down should any embarassed breathing take place; and the greater liability to secondary hemorrhage when the circulation becomes brisk with returning consciousness, are all unfavorable points against the use of this anesthetic throughout the operation. When the patient has been placed well under ether, however, small quantities of chloroform may with great advantage be given to keep up the anesthesia."

The work throughout is free from padding, and may as a whole be heartily commended both to the student and the practitioner.

## THE MICROBIOLOGY OF ACUTE PERITONITIS.

COURTOIS-SUFFIT, in his recent monograph on "Diseases of the Peritoneum"[1] classes first in order among the pathogenic microbes in peritoneal inflammations the bacillus coli communis. This micro-organism is a facultative anaërobic, a normal inhabitant of the intestines, but pathogenic under morbid conditions such as occur in all kinds of peritonitis of intestinal origin. Its presence has long been recognized in peritoneal exudations, while it is constantly found in septic peritonitis following intestinal wounds, perforating (gastric, typhoid, enteric, appendicular) ulcers, ischio-rectal abscess, cancer of the colon, hernia, thrombosis of the mesenteric vessels, etc. It has been affirmed[2] that under certain circumstances, as when disordered circulation, strangulation, extreme fecal distention, undue pressure or mechanical injury has impaired the integrity of the bowel and lowered tissue-resistance, this bacterium may become migratory, gain the peritoneum, and excite inflammation. Cornil found such bacteria actually in the substance of the wall of a partly necrosed intestine.[3] The possibility of such migration may explain many cases of so-called idiopathic peritonitis attending stercoral impaction, severe bowel inflammations, etc.; the germs passed through the intestinal walls and provoked peritonitis. It is doubtful if peritonitis has ever followed cystitis, yet Achard and Renaut have proved the identity of the colon-bacillus with the bacterium pyogenes of the bladder (Courtois Suffit).

The pneumococcus has very rarely any causal relation to acute peritonitis, whether the infection occur as a sequel to pneumonia or independently of that disease.

[1] Traité de Médecine, t. iii, p. 606.

[2] American Gynecological and Obstetrical Journal, January, 1895, p. 58. (Article by Dr. Richard Douglas.)

[3] Loc. cit., p. 59. The observation has been confirmed by Clado, and independently by Fraënkel in relation to cases of peritonitis following strangulated hernia, even when occurring apart from any solution of continuity or gangrene of the intestine; the microbes, in fact, *pass through* the intestinal walls which are so modified in their vitality as to offer them little resistance.

The streptococcus pyogenes has been found in the pus of a great many cases of peritonitis, where it existed to the exclusion of every other micro-organism (post-operative and puerperal peritonitis). Cases of streptococcus-peritonitis following erysipelas of the face have been reported by Cheurlin [4] and others, and in rare instances this disease has succeeded scarlet fever, a malady in which the streptococcus seems to have a predominant part.

Penetration, by the microbes, of the abdominal wall is said in rare instances to have taken place in cases of erysipelas of the abdominal integument; and puerperal peritonitis from extension of a streptococcus-inflammation from the pelvic peritoneum and uterine cavity is of very common occurrence.

Acute peritonitis has been in numerous instances ascribed to the staphylococcus (aureus and albus) found apart from other micro-organisms in the pus (Fraënkel). In other cases, the staphylococcus was associated with the streptococcus, or with the rod-shaped or round micro-organisms of putrefaction. The saprogenous microbes seem to have been influential in certain cases. The colon-bacillus is probably a bacterium of saprogenous character, with possibilities of greatly exalted virulence.

Suppurative salpingitis is a recognized cause of acute peritonitis. When the salpingitis has developed under the influence of the true pyogenic organisms (streptococci and staphylococci), a generalized peritonitis which is almost always fatal follows the rupture of the tube. The case is not so serious, according to Bumm, when the salpingitis succeeds gonorrheal infection, and in which the exudates contain only the diplococcus of Neisser. The latter micro-organism, Bumm says, can exert its action only on mucous membranes, being inoffensive to the serosa and cellular tissue. Naturally, then, the rupture of such a pus tube, or the leakage of pus from the fimbriated end into the peritoneum would not be followed by a general septic peritonitis, but the exudate would be resorbed like any aseptic fluid.

With regard to the effect on the peritoneum of rupture of one of the hollow organs of the abdomen, the result, as Courtois-Suffit remarks, is variable, depending on the presence or absence of microbes in the extravasated fluid. The bursting of the healthy bladder with effusion of normal urine into the peritoneal cavity is not followed by acute peritonitis. This has been proved by the experiments of Gosselin, Robin, Albarran, and others. The case is altogether different when the urinary passages are infected and the urine contains the streptococcus pyogenes, the septic bacterium of Clado, or other pyogenic organisms.

What is true for the urine is equally exact for the bile, as abundant experiments on animals have shown. This is made plain by Dupré in his now classic work on "The Biliary Infections." But the biliary passages and the bile may become infected from various causes, and rupture of the gall-bladder would then be followed by a fatal peritonitis. A case of this kind has been reported by Fraënkel, who found in the peritoneal exudate streptococci and staphylococci.

Penetrating wounds of the stomach allowing small quantities of gastric juice and other contents to escape into the peritoneal cavity are not necessarily fatal if the wound be not large, and the leakage not great. The stomach is not a good culture field for pathogenic microbes, the gastric juice being aseptic and antiseptic. The result of a penetrating wound of the stomach or a perforating ulcer will, of course, be far graver if the stomach or its secretions has become pathologically altered, and if there be considerable escape of its contents into the peritoneum.

When the intestine is the source of the peritoneal lesion, whether by traumatism or profound ulceration, the peritonitis is likely to be spreading and fatal, especially if there be a massive infection. The microbes which are chiefly concerned are those which are found in a normal state in the intestine; the coli-communis, the bacillus albuminis (Bunstock), the bacillus mesentericus vulgatus, the septic vibrio of Pasteur. There is a law laid down by Malvoz, which, as far as it is accurate, may be of help from a medico-legal point of view. If the peritonitis be of intestinal origin, the bacterium coli will show it; if it be of uterine origin (as when consecutive to abortion), the presence of the streptococcus will prove this, even though there should be no visible inflammatory lesions of the genital organs.

[4] Thèse de Paris, 1879.

## THE SIXTEENTH ANNUAL REPORT OF THE MASSACHUSETTS STATE BOARD OF LUNACY AND CHARITY.

INCLUDING the short life of "that grotesque alliance," the State Board of Health, Lunacy and Charity, the Massachusetts Board of Lunacy and Charity will have been in existence sixteen years next June. Thirty-five members have been appointed to the board, of whom one has recently resigned, although his term of service expires next June. Eighteen others have resigned during their terms of service; two have died in office. The membership of the board is nine; and they serve without pay.

The apparent readiness of gentlemen to decline service on the board cannot be from a failure of the legislature to provide opportunities for usefulness or liberal appropriations of money.

The powers and duties of the board include the supervision, visitation, and inspection of all public and private institutions for the insane, the State Almshouse, the State Farm, the three State Schools, the city and town almshouses containing insane inmates, and all places where State paupers are supported; the care and custody of insane patients boarded in families; the supervision of juvenile offenders, including attendance in court in the interest of such offenders; the care and maintenance of indigent and neglected children boarded in families, and the visitation of all minor wards of the State in families; the licensing of boarding-houses for infants, and the prosecution of

cases of violation of the infant-boarding law; the removal of non-settled paupers to other States and countries; the administration of the laws concerning the support of State paupers by cities and towns; the prosecution of cases of bastardy among non-settled persons; the tabulation of returns from overseers-of-the-poor of paupers supported by towns; and the care and maintenance of alien immigrants falling into distress within a period of one year from the time of their landing. In addition to its power of transfer of patients from one State charitable institution or hospital for the insane to another, the board has the power of discharge from the State Almshouse and sole power of discharge from the State Farm and the State Primary School, and also shares with the trustees of the hospitals for the insane the power of discharge therefrom.

The sixteenth report[1] of the board is chiefly a detailed statement of excellent work for the year. The insane at the close of the year were 5,551 in hospitals and asylums, 809 in town almshouses, 211 in private families. The children cared for were 524 in institutions, 1,459 self-supporting in families, 582 at board in families. There were 159 licensed houses for boarding infants, of whom there were 1,156 including 526 illegitimate. The visits to the sick poor were 9,316, and these involved 497 persons and 246 patients where provisions had to be made on account of diseases dangerous to the public health — 125 small-pox, 36 scarlet fever, 23 diphtheria and 10 measles.

Since State supervision of immigration began, in 1848, the number of immigrants at the port of Boston has been 986,460.

The State Institutions under the general supervision of the Board are the State Primary School, the Lyman School for Boys, the State Industrial School for Girls, the State Almshouse, the State Farm, the Hospitals for the Insane at Worcester, Taunton, Northampton, Danvers and Westborough, the Asylum for the Chronic Insane, the Hospital for Dipsomaniacs and Inebriates. The School for the Feeble-Minded and the Hospital Cottages for Children are only partly under State Control. Its supervision of the Boston Lunatic Hospital, the McLean Hospital, and seven private insane asylums is little more than nominal.

Much is said in the report in praise of the McLean Hospital for the Insane, where, in the last thirteen years, 457 of the patients admitted have been without certificates of commitment, under the admirable law of 1880 which allows voluntary admissions to hospitals for the insane. The many excellent features of this hospital place it in the front rank of institutions of its kind in the world.

Such a vast amount of labor naturally implies faithful and intelligent service on the part of highly-trained salaried officers and their assistants, and devoted work by the members of the board. The visitation of young girls boarded in families is by eighty-one carefully chosen ladies who live near enough to their wards to be familiar with their needs and who volunteer their services.

The board makes several recommendations for legislation in which the medical profession has an opportunity to show its interest; providing for the appointment of medical examiners in lunacy;[2] providing for medical certificates of lunacy to be issued by the State Board; amending the law which prevents physicians of insane hospitals from certifying to cases of insanity; making separate provisions for adult epileptics.

## HAFFKINE'S INOCULATION AGAINST CHOLERA.

AT the Indian Medical Congress Haffkine made a report on his method of inoculation against cholera, and the results attained up to the present time. The virus which he employs is obtained by the cultivation of attenuated cholera bacilli in the peritoneal cavities of guinea-pigs. He portrayed the difficulty which he had had in overcoming the prejudices of the people against inoculation; a year had passed before he was able to carry out his method in suitable places, and under favorable conditions.

In upper India he had inoculated 22,603 persons; in Bengal, Behar and Assam, 9,563; in all, 32,166, of which records were kept. Yet the month of March, 1894, was the first in which he was able to perform 1,000 inoculations during a moderately severe epidemic in Calcutta, and in the part of the city where the epidemic was most prevalent. In all, 3,478 persons were inoculated in Calcutta during 1894.

The method pursued was that of inoculating a part of the members of certain households, in which an outbreak of cholera was thought likely to take place. In 13 houses, 85 out of 181 persons living under the same sanitary conditions were inoculated. Among those inoculated 1.18 per cent. died of cholera; of those not inoculated 15.03 per cent. "took" the disease, and 11.63 per cent. died. In August, 1894, cholera broke out in the garrison at Cawnpore, 872 strong; of this number 75 had been inoculated thirteen months before. There were 19 cases and 13 deaths, all among the soldiers who had not been inoculated. The results in Gaya jail were also favorable, those in Lucknow less so, where 18.7 per cent. of the cases were among the non-inoculated, and 13.53 per cent. among the inoculated. The following table gives a summary of the results at Calcutta, Gaya, Cawnpore and Lucknow.

| | Non-Inoculated. | Inoculated. | Total. |
|---|---|---|---|
| Number of observations | 1,735 | 500 | 2,235 |
| Cases | 174 | 21 | 193 |
| Per cent. | 10.63 | 4.20 | |
| Deaths | 113 | 19 | 132 |
| Per cent. | 6.51 | 3.80 | |

Haffkine holds that if any conclusion can be drawn from this tabulation, it must be a favorable one. At all events his experience so far has demonstrated the entire harmlessness of the inoculations.

[2] When we use the objectionable words lunacy and lunatic, it goes without saying that we quote them.

## MEDICAL NOTES.

OBSTETRICAL SOCIETY OF CINCINNATI. — At its recent annual meeting the following officers were elected for the ensuing year: President, Dr. A. W. Johnstone; Vice-President, Dr. Sigmar Stark; Secretary, Dr. E. S. McKee; Corresponding Secretary, Dr. W. D. Porter; Treasurer, Dr. Geo. E. Jones.

DIPHTHERIA IN LONDON AND NEW YORK. — During the last week in January there were but 29 deaths from diphtheria in London, a progressive fall having taken place from 50 deaths in the week ending January 5th. The close correspondence in time with the report given in the last number of the JOURNAL of a falling off of 25 per cent. in the cases of diphtheria in New York City during the same period is extremely interesting. If, as is thought by the health-officers of New York, the abatement in that city is due to the use of antitoxin, may not the decrease in London be due to the same cause? It is also noteworthy that in Paris, between January 20th and 26th, there were but 7 deaths from diphtheria, the average for past years being 33.

"COMMITTEE ON LITTER." — The following members of the "Committee on Litter," appointed by the Association of Military Surgeons of the United States, to report a desirable form of military litter for the comfortable, safe and expeditious transportation of the sick and wounded, solicit from medical officers of the National Services and the National Guard of the several States, suggestions, plans or models of such an appliance, to be delivered to either of them, on or before the first of April, 1895: Albert L. Gihon, Medical Director, U. S. Navy, U. S. Naval Hospital, Washington, D. C.; John Van R. Hoff, Major and Surgeon, U. S. Army, Governor's Island, New York Harbor; Myles Standish, Captain Ambulance Corps, M. V. M., 200 Dartmouth Street, Boston, Mass.

### BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, February 20, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 82, scarlet fever 40, measles 29, typhoid fever 6.

CONVENTION OF SUPERINTENDENTS OF TRAINING-SCHOOLS FOR NURSES. — The second annual convention of the American Society of Superintendents of Training-Schools for Nurses was held in Boston during the three days beginning Wednesday, February 13th. The programme of the convention consisted of business meetings, at which papers were read on subjects connected with the training of nurses and the management of training-schools. "A Uniform Curriculum of Study for Training-Schools" was the subject of a paper and discussion. A reception was given to the Society at the Boston City Hospital, and another at Perkins Hall, by the Graduate Nurses Association. Visits were made by the Society to the hospitals of Boston and vicinity. The Superintendents of most of the larger training-schools of this country attended the convention.

THE BOSTON TRAINING-SCHOO FOR NURSES. — The report of the Boston Training-School for Nurses, attached to the Massachusetts General Hospital, for the year 1894, has just been issued. The year is considered to have been a satisfactory one, the character of the pupils having been of a high standard, and the instruction given having been broadened and increased in interest. The expenses of the school, however, have been unusually heavy; and, owing to the death or absence of several annual subscribers, the income has largely fallen off. The treasurer reports a deficit for the first time. The need of funds is therefore a very serious one, and for the lack of them the usefulness of the school is curtailed in many directions. The school is not a corporate part of the Massachusetts General Hospital, and the heavy running expenses must be met out of its own funds. Subscriptions of any amount from friends of the school are desired. The accepted probationers were 37 out of 834 applications. 23 were graduated during the year. An important development in the instruction given was the establishment of the cooking-school on a new basis. This work had hitherto been done outside the hospital. Through the efforts of the directors and the kindness of the hospital trustees the cooking-classes are now held in the hospital kitchen.

ALUMNÆ ASSOCIATION OF BOSTON TRAINING-SCHOOL FOR NURSES. — Fifty graduates of the Boston Training-School for Nurses met at the Thorndyke, Thursday afternoon, February 14th, and formed an Alumnæ Association. The Association is to be called "The Alumnæ Association of The Boston Training-School for Nurses, attached to the Massachusetts General Hospital." Miss Maria B. Brown, superintendent of the school, was elected President of the Association by acclamation. The other officers elected were Miss Alice O. Tippett, Vice-President; Mrs. D. H. Kinney, Treasurer; Miss Florence F. Rice, Secretary; Miss Blanche M. Thayer, Miss Elizabeth McPhail, Miss Lucy Webster, Miss Carline Cayford, and Mrs. Mary Bryant, were appointed as a special committee to assist in framing a constitution. Miss Davis, Superintendent of University Hospital, Philadelphia, and Miss Sophia Palmer, of Washington, D. C., who have been prime movers in bringing about the meeting, were present, and stated the object of the meeting and need of an association. Miss Richards and Miss Anna A. Maxwell, both former superintendents of the school, were also present; and each in a brief address expressed her interest and sympathy in the movement, urging the necessity of alumnæ associations to keep graduates of a school in touch and sympathy with each other, also to foster a kindly feeling towards members of the nursing profession who are graduates of other schools. The meeting was then adjourned to meet March 14th, hour and place of meeting to be appointed by the president of the Association.

Diagnosis of Diphtheria at Hartford, Conn. — The Hartford Board of Health has provided facilities for the bacteriological diagnosis of diphtheria in that city, being the first city in the State to take this step in public hygiene.

Notification of Contagious Diseases in Connecticut. — The *Monthly Bulletin of the State Board of Health of Connecticut*, for January, calls the attention of the local health officers to the fact that reports as to the prevalence or non-prevalence of contagious diseases have been made to the State board by only about one-half of the towns in the State. Unless such reports are sent in, it is impossible to obtain a knowledge of the public health sufficient to ensure prompt and efficient action by the State board for the restriction and control of contagious diseases. It is also important, when no cases of contagious diseases have occurred, for the State board to be notified of the fact. A failure to make prompt and accurate monthly returns to the central board is hardly indicative of a proper conception of his duties on the part of a local health officer.

NEW YORK.

Another Case of Small-Pox. — The first report of a case of small-pox in the city since January 29th was made on February 12th. At that date there was but one small-pox patient at the Riverside Hospital on North Brother Island.

Dr. Vander Veer Appointed Regent. — On February 13th Dr. Albert Vander Veer, of Albany, was elected by the legislature Regent of the University of the State of New York.

The Hospital Book and Newspaper Society. — The twentieth annual report of the Hospital Book and Newspaper Society states that the amount of reading matter distributed during the past year was as follows: Books, 6,310; magazines, 18,853; illustrated papers, 63,326; newspapers, etc., 152,385.

Death-Rate of New York City. — The number of deaths reported during the week ending February 16th was 959, an increase of 37 over the mortality of the preceding week, and 95 above the average of the corresponding weeks for the past five years. The number of deaths from diphtheria was 29, a decrease of 10 from the week ending February 9th.

## Miscellany.

### THE MISSING LINK FOUND AT LAST.

Dr. D. G. Brinton writes to *Science* under this title, and says that Dr. Eugene Dubois, a Dutch army surgeon stationed in Batavia, Java, has found the "link." He, the surgeon, describes three fragments of three skeletons which have been exhumed from the early pleistocene strata of Java, and which introduce to us a new species, as well as a new genus and a new family, of the order of primates, placed between the *Simiidæ* and *Hominidæ*.

The material, we are told, is sufficient for a close osteological comparison. The cubical capacity of the skull is about two-thirds that of the human average. It is distinctly dolichocepalic, about seventy degrees, and its *norma verticalis* astonishingly like that of the famous Neanderthal skull. The dental apparatus is still of the simian type, but less markedly so than in other apes. The femora are singularly human. They prove beyond doubt, says Dr. Brinton, that this creature walked constantly on two legs, and when erect was quite equal in height to the average human male. Of the various differences which separate it from the highest apes and the lowest men, it may be said that they bring it closer to the latter than to the former.

The line of descent, according to Dr. Dubois is: *Prothylobates, Anthropopithecus sivalensis, Pithecanthropus erectus, Homo sapiens.*

The discovery of Dr. Dubois leads him to think that man originated on the southern slopes of the Himalayan chain, which is, after all, not so far from the Garden of Eden; and is just south of the present abode of the mystical Mahatmas. We trust that Dr. Dubois is *homo sapiens.* — *Medical Record.*

### BICYCLE RIDING FOR WOMEN.[1]

"At the meeting of the Société de Médecine Publique, Mme. Gaches-Sarrante read a paper on the utility of the bicycle for women. For the last three years she has been practising this masculine exercise to the great benefit of her health. Alluding to the costume to be adopted, she insisted on the fatigue produced by the corset; the least up-hill provokes oppression from the stricture of the thorax. As regards the genital organs, all acute inflammation should forbid the use of the machine; but when the lesions were chronic, moderate exercise might be permitted and even enjoined. In any case, riding is much less fatiguing than standing or walking. Salpingitis, or chronic salpingo-ovariatitis, do not constitute a counter-indication, and in cases of chronic peri-uterine inflammation the bicyclette can replace with advantage the Swedish method of massage.

"Bicycling exercises, consequently, a healthy influence on the physical nature of women; they sleep better, digest better, their chest expands so as to find it necessary after a short time to enlarge the corsage of their robes. Mme. Sarrante concluded by drawing a vivid picture of the moral rôle of the bicyclette, the only physical exercise that husband and wife can take together."!

### TOTAL RESECTION OF THE STOMACH.

Langenbuch reports in the *Deutsche med Wochenschrift*, 1894, No. 52, two cases in which almost the entire stomach was removed for carcinoma, with one recovery and one death. The successful case was that of a woman fifty-eight years old. The new growth occupied the posterior wall of the stomach, but there were nodules on the greater curvature, extending into the greater omentum. The stomach was brought out through the abdominal wound, and about seven-eighths of it removed. On suturing the cardiac to the pyloric

[1] From the Paris Correspondence of the Medical Press and Circular, December 26, 1894.

stump, the newly formed stomach was about the size of a hen's egg. It was fixed by gauze and sutures in the abdominal wound. The operation occupied one and three-quarter hours, and very little chloroform was used, the anesthetist claiming that only ten drops (!) were employed. On the evening of the day of the operation a little milk and egg with sugar was given by mouth and retained, and on the day following the operation liquid nourishment was given repeatedly. On this day the pulse and temperature were so that the patient was regarded as lost, but fell to normal on the following morning. The patient had a slight attack of pneumonia during convalescence but gained twenty-two pounds before she left the hospital several weeks after the operation.

In the second case, which was operated in a similar manner, the stomach was so softened, that rupture at the cardiac extremity took place during its removal. The opening was closed by sutures, however, and the operation completed. On the second day the dressings were found soiled with gastric contents, and it was evident that some of the sutures had given way. An attempt was made to introduce a tube through the gastric fistula into the duodenum, but the effort to accomplish this so disturbed the parts that local peritonitis occurred, resulting in death on the sixth day. At the autopsy the peritonitis was found to be local, and not to have involved the general peritoneal cavity.

### THE INVALID TOURIST.

A Bête Noir in Southern California.

REDLANDS, SAN BERNARDINO CO., CAL., February 3, 1895.

MR. EDITOR: — For the past ten years invalids, especially consumptives, have frequented Southern California in great numbers. The majority of these were in the last stages of the disease before leaving home, and expected the climate to work a miracle. Given up by their physicians, and beyond the reach of any relief from medicines, these unfortunates have made the long and tedious journey to the Pacific Coast only to die there, or to make the same hurried journey back again for the consolation of dying among friends. Hundreds of them have died in Pullman cars or at way stations *en route*.

During these same ten years, and particularly during the last three or four, the press, including medical journals, magazines and newspapers, has been full of articles upon the danger of contagion in cases of consumption. In this way the public has been educated to a horror of the disease. It is asserted that one-seventh of the human race are dying of consumption. And the fact has been carefully impressed upon the minds of the remaining six-sevenths that any chance breath may fill their lungs with virulent microscopic germs floating in the air in the neghborhood of consumptives.

Now, there are in Southern California few sanitariums. Either from a lack of patronage or from unskilful management, such institutions have not flourished. Not one consumptive in a hundred will go to a health-resort, managed strictly as such, a place where he can be properly cared for and nursed, and kept from contaminating the atmosphere which well people are supposed to breathe. Not one in a hundred will admit that he has consumption. It is always "a little throat trouble," or "a touch of *la grippe*." Hence it happens that nearly all of these invalids expect to be received into resort hotels, already partially filled with pleasure-seekers, investors, and residents of the country. These have been educated, as just stated, to a fear of consumption second only to the popular fear of cholera or yellow fever.

As a class, the keepers of these hotels are humane men and women. They desire to do what is right and to assist the unfortunate; but it puts one of them in a very trying position when a guest arrives whose chances of living a week are perhaps not one in ten, and whose cavernous cough can be heard the length and breadth of the dining-room. Within twenty-four hours after such a guest arrives a dozen healthy, and therefore desirable, guests will probably call for their bills and seek other quarters. What is the landlord to do in such a case?

Tell the would-be guest that he cannot be received, of course. Yes, but that might result in great hardship. The man may arrive in the evening. The other hotels may be filled, or, if not, are equally unwilling to receive invalids. Rooms may have been engaged in advance, the coming guest neglecting to say that he brings a plague with him. It is hardly polite or dignified to inform him, after he has already been cordially welcomed by mail, that the rooms reserved for him are occupied by another. It is equally hard to "come out flat-footed," and tell a despairing man, perhaps accompanied by an equally despairing wife or mother, that he cannot be given food and shelter.

Send him to some private family, suggests another. That would be very well for him, if families would receive him. But they are even less willing to do so than the hotels; and, being private families, they can easily refuse, although it may be understood that they "take boarders." There are no families in Southern California that are not educated regarding the danger from consumption, and there are very few willing to run that danger for any amount of money.

The result usually is that the guest is received, temporarily at least. If he is alone the landlord looks after him as best he can in the press of his other duties. If he dies the landlord remains with him, as he crosses the dark river, and gives him the feeble aid of a friendly hand-clasp. No one can be hired for this duty. Then he wires the unfortunate's family, arranges with the undertaker for the things that must be done, and writes a letter to the dead man's home, describing his last hours. There is nothing fanciful in this picture. It is understated rather than overdrawn, and it occurs every few days during the tourist season. When the duties mentioned are all done, there remains the task of cleaning and disinfecting the room lately occupied. Every article of furniture must be taken out. The walls and ceiling must be cleaned with disinfectants, and after this is done, and the articles removed are restored to their places, the room must remain vacant perhaps a fortnight, until it loses its odor of drugs and the guests forget that there has been a death in it. For all this worry, expense and delay, as a rule, the landlord receives nothing whatever.

If the invalid is accompanied by friends the landlord, of course, has less responsibility. But the strain upon his sympathies, if he has any, is often even greater. "What are you doing here?" I asked one day of a friend at a railway station. He pointed at a long, narrow box, which the trainmen were placing in the baggage-car, and then at a couple of girls who stood at the door of the depot, evidently prepared to take the overland train.

"Came over to see them off," he said. "Poor children. It's a sad case. They came out with us from Chicago a week ago. That's their mother in the box. Been here just a week. Going back with the body to-day. Excuse me, I must see them aboard."

There the two children were, brave little things, the elder perhaps sixteen, but very girlish, the other three or four years younger. The father was in Chicago, doubtless unable to leave his business. My heart ached for them as I thought of the mournful journey before them. But nothing more could be done to help them.

The reflection which occurs to a layman in such a case is naturally about as follows: "Why was that woman permitted to go West? Was not her death an absolute

moral certainty in the mind of her physician, and should he not have insisted upon her remaining at home? Why add to the horrors of her inevitable and speedy death the tortures of that long journey westward and the dread overshadowing her last hours, of that even more wretched trip homeward, which her children were obliged to take?"

I have known twelve of these deaths to occur in a single little country hotel, of forty rooms, in one season. Sometimes the proprietor of such an hotel is put in a position where it is absolutely impossible for him to entertain such guests. It may mean simply ruin for him. Only the other day I asked a certain young man how they were getting along at a hotel in which I had a friendly, but luckily not a financial, interest. "Got another consumptive," he said. "Bad case this time. Everybody ready to go out through the windows." In this instance the landlady became desperate, and finally told the invalid and his wife that they must leave the house. In her excitement and dread of the interview she probably lost her usual tact and said more than she intended. At least there was considerable talk about the occurrence. A good Samaritan, hearing of it, took the man home, saying that he should be cared for as long as he lived. That period was just three days, and he was not in California more than two weeks.

Thousands of people are living in Southern California who went there in early stages of disease and received a benefit from the climate without which they would probably have perished. Scores of others would be alive to-day, who are dead, but for that curious mania for overtaxing their strength which seizes so many who begin to recover. A long walk, a fatiguing horseback-ride, exposure to the air half an hour later than usual, some trivial thing of this sort, undoes the slow and careful work of months, and kills many a promising convalescent. Equally fatal is the tendency to homesickness. Many an invalid has partially recovered his health, and then sacrificed it for a single visit to his former home, incurring some fatigue, or risking some exposure that exhausted the slender store of dearly acquired vitality and brought on a fatal relapse.

Of the several hundred cases of advanced consumption which have come under my personal observation, during a residence of seven years in Southern California, I should say that about one per cent. are cured. I have an acquaintance, a hale and hearty, rugged man, who is said to have been a skeleton when he reached the country. I met another man, a policeman, in Los Angeles, a few years ago, who told me a singular story. He said that when he reached that Mecca of the invalid, Los Angeles, he was suffering from what was pronounced a case of tuberculosis. He could barely walk, and was too weak to carry his valise from the 'bus to the hotel office. He had some twenty thousand dollars, and might have stopped, and died, at one of the best hotels. Instead, he gave the money into the care of a friend, and went, alone, into the high mountains back of San Bernardino. He built a rude hut, and lived almost entirely upon trout and quail caught by himself. When I knew him he was tall, erect and ruddy, and no one would have thought that he had ever been an invalid; but I believed his story to be true.

The third case that I believe to be recovery from pronounced tuberculosis as a result of residence in Southern California, I have watched with interest for three years, and desire to mention at some length, as it shows how invalids coming to Catifornia should live. In this instance consumption followed an attack of pneumonia. The invalid was about thirty years of age, and had possessed a splendid constitution, uninjured by disease or dissipation of any kind. A young woman, strong, cheerful and perfectly well, thought enough of him to marry him after his illness began and to come to California with him.

Their physician advised this couple to live in a tent, and they did so. The first summer was a very hard one. The weather became too warm in the valley and they went to the mountains. Here the invalid's strength failed so rapidly, on account of the heat, that they were obliged to make a hurried trip to the coast, where he recuperated. But it seemed for a long time very doubtful whether he could rally. In the following fall they abandoned their small tent for a more elaborate "tent house," in which they lived for more than a year. This was destroyed by fire, and they built a still better one. It has a foundation and floor like any house. For five or six feet from this the walls are of wood, the rest of the way they are of canvas. Tbere is a double roof, one of canvas and another of the ordinary sort, with about two feet of air space between. The interior is divided into five or six handily arranged rooms. It is finished in red wood, varnished but not painted. The lot, house and furniture cost about seven hundred dollars. It is warmer in summer than a wooden house would be, but it cools very rapidly at night. A single fire keeps it warm in the severest winter weather. Living in it is the next thing to living out-of-doors. The owner is always sure of pure air without danger of draughts. He is recovering a degree of health, after a long and tedious struggle, a difficult period of incessant watchfulness. He has a small fruit-ranch upon which he spends some of his time in out-door labor. But even now, three years after his first illness, when his cough has nearly left him, he practises infinite precaution, is never out of his home after four o'clock, except in mid-summer, and, in matters of dress, etc., never forgets for an instant that he is an invalid. Profiting by the experiences of others, he has no desire to return to the East, even for a short period. He will doubtless make as complete a recovery as is possible after so severe an attack of so virulent a disorder.

The logical conclusion from these facts would seem to be that persons in an advanced stage of consumption might better remain at home than to clutch at that last straw of hope, a journey West; and that those who seem to have a fair "fighting chance" against this dread destroyer, who go West, should go with a better understanding than is usual of the conditions awaiting them on arrival. Since these people will not live together, in hospitals or sanitariums, each cherishing the delusion that he is not a victim to consumption, each believing that he would risk infection by associating with consumptives, they should come prepared, as far as possible, to live by themselves. There are always cottages to be rented in any Southern California town, if the invalid does not care to follow that best plan of all and to construct a tent-cottage. Housekeeping is cheaper than hotel living and infinitely better. The patient may be more quiet, and he may have such articles of food prepared as he desires, a very decided advantage over hotel life. Southern California is full of warm-hearted, sympathetic people, and no one following the plan suggested need fear that he will be totally isolated among strangers. On the contrary, he will soon learn that his course will be approved, and that he will find friends.

But to come, as I have seen hundreds, alone, to a strange town and an unfamiliar way of life, to take a cheap room, in a cheap hotel and there to live upon cheap food, hastily served, to spend day after day lounging in the sunshine, or, in bad weather, confined to the narrow walls of a little room, in either case with insufficient exercise, to shun all bearing the same unmistakable marks of a terrible disease, to be shunned by all others — such a course is simply placing one's self in the clutch of death, like a mouse in the claws of a cat, to be a plaything for a little while, before the final, inevitable blow. Such a procedure is of benefit only to the railroad companies and the undertakers; and the sensible, thinking people of Southern California, who see it so often, are coming more and more to wonder at the ignorance which prompts it. In many cases absolutely beyond help the victim is a poor man, and the money expended in this useless pilgrimage might far better be kept for a few comforts to ease his last days and for the support of his family. In thousands of other cases, where the element of expense is of no importance, the result is the same; and the journey, undertaken, perhaps, with high hopes, and followed out with every attention and comfort that money can buy, ends in swift and crushing disappointment.

Very truly yours,

Wm. M. Tisdale.

## METEOROLOGICAL RECORD,

For the week ending February 9th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer | Thermometer. | | | Relative humidity. | | | Direction of wind. | | Velocity of wind. | | We'th'r.* | | Rainfall in inches. |

Deaths reported 2,709: under five years of age 925; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 288, acute lung diseases 539, consumption 344, diphtheria and croup 161, diarrheal diseases 24, scarlet fever 23, typhoid fever 22, whooping-cough 19, erysipelas 12, cerebro-spinal meningitis 11, measles 10, small-pox 6.

From typhoid fever Philadelphia 8, Washington 6, Brooklyn, Cincinnati and Lowell 2 each, New York and Boston 1 each. From whooping-cough New York 8, Brooklyn 5, Philadelphia 2, Fall River, Haverhill, Quincy and Northampton 1 each. From erysipelas New York 6, Brooklyn 3, Providence 2, Nashville 1. From cerebro-spinal meningitis New York 6, Holyoke, Boston and Pittsfield 3 each. From measles New York 6, Philadelphia, Brooklyn, Cleveland and Springfield 1 each. From small-pox New York and Philadelphia 3 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530, for the week ending February 9th, the death-rate was 19.7. Deaths reported 4,000: acute diseases of the respiratory organs (London) 377, whooping-cough 76, diphtheria 70, measles 48, diarrhea 45, fever 33, small-pox (London) 2.

The death-rates ranged from 11.8 in Croydon to 27.9 in Liverpool; Birmingham 16.0, Bradford 19.8, Gateshead 21.8, Huddersfield 16.8, Leeds 20.3, Leicester 16.9, London 19.0, Manchester 23.5, Newcastle-on-Tyne 21.2, Nottingham 17.0, Portsmouth 14.6, Sheffield 18.6, Sunderland 20.4, Swansea 22.0.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 9, 1895, TO FEBRUARY 15, 1895.

COLONEL CHARLES C. BYRNE, assistant surgeon-general, is relieved from duty as medical director, Headquarters, Department of Dakota, and announced as medical director, Headquarters, Department of the East.

LIEUT.-COL. HENRY R. TILTON, deputy surgeon-general, is announced as medical director, Headquarters, Department of Dakota.

FIRST-LIEUT. GUY C. M. GODFREY, assistant surgeon, will proceed without delay from Fort D. A. Russell, Wyoming, to Fort Omaha, Nebraska, and report for temporary duty.

## OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDING FEBRUARY 15, 1895.

PURVIANCE, GEORGE, surgeon. Detailed as chairman, Board for examination of assistant surgeons for promotion, to convene in Washington, D. C., March 11, 1895. February 8, 1895.

HAMILTON, J. B., surgeon. Granted leave of absence for six days. February 7, 1895.

AUSTIN, H. W., surgeon. Detailed as member, Board for examination of assistant surgeons for promotion. February 8, 1895.

IRWIN FAIRFAX, surgeon. Detailed as recorder, Board for examination of assistant surgeons for promotion. February 8, 1895.

STIMPSON, W. G., passed assistant surgeon. To assume temporary command of Service at Port Townsend, Washington, during absence of Passed Assistant Surgeon J. O. Cobb. February 13, 1895.

EAGER, J. M., assistant surgeon. Ordered to examination for promotion. February 9, 1895.

BLUE, RUPERT, assistant surgeon. Granted leave of absence for six days. February 13, 1895.

NORMAN SEATON, assistant surgeon. Ordered to examination for promotion. February 9, 1895.

## SOCIETY NOTICE.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Obstetrics and Diseases of Women will meet at 19 Boylston Place, on Wednesday evening, February 27, 1895, at 8 o'clock.

Dr. Cumston: "Report of Case of Osteomalacia; Operation; Recovery."

Dr. S. E. Courtney; "Remarks on Four Cases of Eclampsia Occurring at Boston City Hospital."

Dr. C. H. Hare: "Report of Case of Eclampsia; Death."

GEO. H. WASHBURN, M.D., *Chairman.*
J. M. JACKSON, M.D., *Secretary.*

## RECENT DEATHS.

STEPHEN WALLACE BOWLES, M.D., M.M.S.S., died in Springfield, February 12, 1895, aged fifty-nine years.

PROF. J. GOTTSTEIN, the eminent laryngologist, died in Breslau, January 10th, aged sixty-three. He is best known as the inventor of the curette for adenoid growths, which bears his name, and as the author of an excellent text-book on diseases of the larynx. His original work in laryngology has been of the greatest importance in the progress of that specialty.

## BOOKS AND PAMPHLETS RECEIVED.

The Life-Saving Society, Handbook of Instructions for the Rescue of the Drowning. Third revised edition. 1895.

Transactions of the American Orthopedic Association, Eighth Session, held at Washington, D. C., May 29, 30 and 31, 1894. Volume VII. Philadelphia: Published by the Association. 1895.

## TRAUMATIC GLYCOSURIA.

### Observations Made in Two Hundred and Twelve Cases of Head Injuries.*

BY F. A. HIGGINS, M.D., AND J. B. OGDEN, M.D.

Ever since the time of Claude Bernard, who first experimentally demonstrated the existence of the so-called sugar centre in the floor of the fourth ventricle, head injuries have been recognized as playing a certain part in the etiology of some cases of diabetes. In addition to permanent glycosuria following traumatism of the head, there is another form observed by some writers, and of which a number of cases have been reported. This last is merely transitory, and comes on directly after the traumatism, or in a few days. On the other hand, the permanent form of glycosuria occurs at a period of weeks, or even months afterwards.

In this article very little work has been directed towards this last form. The work recorded here was undertaken with the purpose of establishing whether any relation exists between various head lesions resulting from traumatism and transitory glycosuria. It is obvious that this could be done only by following out a considerable number of cases such as would be seen in a large municipal hospital. Accordingly, the work has been performed, with the permission of the surgeons of the Boston City Hospital, upon all cases of head injuries, regardless of severity, admitted to the hospital wards during the thirteen months beginning December 1, 1893, and ending January 1, 1895, comprising in all 212 separate cases. The observations are the results of frequent and systematic examinations of the urine, obtained as soon as possible after the injury, and continuing from time to time during the patient's stay at the hospital. This was done in order to ascertain if any connection existed between the nature of the injury, whether mild or severe, and the appearance of sugar in the urine. Further, to see if such a condition when it occurred could render any assistance in diagnosis, especially in those not infrequent cases in which the diagnosis may be obscured or doubtful, such as many so-called fractures of the base of the skull, resulting in recovery with no other prominent symptoms than temporary unconsciousness and hemorrhage from the ear. The pathology of the disease is not entered upon at all, but a number of cases in which autopsies were performed are reported in full.

First will be considered the literature of permanent glycosuria, and second, that of transitory glycosuria.

#### LITERATURE.

The literature of permanent traumatic glycosuria is comparatively meagre, yet traumatism is generally mentioned as one of the etiological factors in most works on diabetes.

A few examples of traumatic glycosuria are found in the works of Seegen, Fritz, Rechtlighausen, Fischer, Mahe, Tood, Cyr, Itzigsohn and Leydon; but Charcot is of the opinion that many of these are more often cases of persistent glycosuria than of true diabetes.

Lyman[1] says, "Injuries (and tumors), especially if they involve the fourth ventricle, are often accompanied by the development of diabetes."

Strümpell[2] says, "Glycosuria may result from severe concussion of the brain and fracture of the skull."

Tyson[3] says, "Excepting the injuries to the nervous system, which are known to cause diabetes, our knowledge of its causes are not precise. With regard to the former, it is well known that blows upon the skull, with or without fracture, and concussions, communicated to the brain, spinal cord and vaso-motor centres in other ways, as by falls, are such causes."

Griesinger[4] found that 13 out of 225 cases which he collected were of traumatic origin.

Luce[5] reports the case of a healthy lad who fell while skating, striking the back of his head heavily on the ice, and died shortly afterwards of diabetes.

Friedrichs[6] out of a large number, could only trace eight cases of diabetes to traumatism.

Baccelli[7] reports the case of a young man who became diabetic after a concussion of the brain. At the autopsy a necrobiotic point was found in the centre of the pons-Varolii.

Vogel[8] reports a case of a fireman upon whose neck a beam fell. In a few weeks there followed a severe glycosuria ending in death. At the autopsy nothing abnormal was found in the brain, and it is thought that diabetes resulted from concussion of the spine.

Senator[9] says that mechanical injuries are among the most important of exciting causes, such as concussion of the brain and spinal cord, or even of the whole body. Glycosuria usually makes its appearance in a few hours or days after the infliction of the injury, rarely not until later.

Lasegue[10] reports a case of glycosuria occurring three months after the accident, in a man who fell down stairs, causing cerebral concussion.

Bernstein-Kohan,[11] out of 45 cases traced 25 to head injuries, and reports that sugar does not always appear immediately after the injury. If the sugar appears early, it is very apt to be mild. If late, it may be severe and rapidly fatal.

Spencer[12] says, "Injuries of the head and spinal cord are often the cause of sugar in the urine. The sugar may last for a few hours only, or for a few days. As a rule, it quickly disappears, but in some cases the sugar persists, and the patients begin to be diabetic from the time of the injury."

Brouardel and Richardiere,[13] in an article on "Traumatic Diabetes from a Medico-legal Point of View," state that traumatism is a well-recognized cause of diabetes, and that in a considerable number of cases in head injuries, examination of the urine reveals sugar when it has been before unsuspected.

This completes, in brief, a summary of the literature touching upon the subject of permanent traumatic glycosuria, and is sufficient to establish the fact that traumatism does play a more or less important part in the etiology of diabetes. With respect to traumatic glycosuria of the transitory form, it has been the object of much less notice on the part of medical writers and investigators. In connection with this form, the work reported in this article has been principally performed. In the works of Alladoff, Schiff, Pavey and Eckhardt, this subject receives but a passing notice.

Redard[14] says, "A glycosuria uniformly presents itself after all forms of traumatism of the head, whether accompanied by fracture or not. It may show itself almost immediately after an accident." He quotes eight cases where it appeared in two days, and a num-

* Being one of the two papers receiving a Second Lyman Prize for the year 1894. This Paper will appear in the Boston City Hospital Medical and Surgical Reports, Sixth Series.

ber of other cases where it appeared after a number of weeks. He affirms that sugar, if carefully sought for, is nearly always found.

Robin [15] reports a case of temporary glycosuria following cerebral concussion, sugar lasting four days.

De Pietro [16] says that after wounds and injuries of the head, glycosuria may last from two to eleven days, according to the severity of the lesion. That it appears later and lasts longer in fractures than in simple wounds.

Nuzzi [17] says that glycosuria is more or less constant after head injuries. The time of appearance and the quantity of glucose varies greatly. His results are generally negative. In 115 observations on 39 patients he found glycosuria only three times.

Oppenheim and Eisenlohr [18] have observed the transitory form of glycosuria in a few cases.

Buch [19] reports twenty cases with literature, in which injuries occurred to parts of the head, the glycosuria following, being of the transitory form.

Lancereaux [20] says that glycosuria following traumatism is much less serious than the other varieties. It is temporary, it may disappear in a few days, and it never continues longer than a few months.

This concludes a short review of the literature of transitory glycosuria. It consists merely of mere mention of the existence of such a condition by some writers, and reports of a limited number of cases by others. There seems to have been no attempt made to investigate any considerable number of cases with head injuries, or to trace any connection between the glycosuria and the nature of the head injury. Redard attempted to find a connection between the appearance of pus in the wound of the head and glycosuria, but that any connection between the two existed was denied by De Pietro.

We have tabulated the results of the observations on 212 cases, and have arranged them in classes according to the nature of the head injury, without regard to lesions in other parts of the body; yet whenever there have been such lesions, they have been noted both in the tables and in the description of individual cases. The tables will be found in the paper as published in the City Hospital Report. The description of the individual cases follows:

CLASS 1, includes the simple scalp wounds and other minor head injuries.

CLASS 2, scalp wounds with bone exposed.

CLASS 3, cases of concussion, meaning those followed by loss of consciousness without fracture.

CLASS 4, includes fractures of the vault of the skull.

CLASS 5, fractures of the base of the skull.

### CLASS I.

CASE 24, CLASS 1. J. D., male, age forty, laborer. Service of Dr. Cushing. Nine days before entrance was struck on the head by an iron bar, sustaining a scalp wound three or four inches long. There were ten stitches taken in the wound at that time. Three days later erysipelas of the face and scalp developed. On entrance, beside the erysipelas, a discharging sinus was found at one point in the unhealed scalp wound. The patient was discharged on the fifteenth day, the erysipelatous blush having entirely disappeared, and only a very slight discharge from the wound.

*Urine.* — The urine was examined the day following entrance, but no sugar found. Two days later, (twelfth day after injury and ninth day after the appearance of erysipelas) the urine had a specific gravity of 1.020, and contained a slight trace of sugar, it being, however, too slight to quantitate. This trace of sugar continued for two days, then disappeared, and was not found again during his stay in the hospital.

There is obviously some doubt as to the cause of the sugar in this case. It appeared for the first time twelve days after the injury, and at a time when the erysipelas was rapidly improving. It would appear, however, as if the erysipelas had an exciting factor in the production of the sugar, yet it may have been due directly to the injury, even though the sugar did not appear for twelve days. Brouardel and Richardiere report four cases of injury to the head where the sugar did not appear until from one to two weeks after the injury.

CASE 27, CLASS 1. W. E. T., male, age four years. Service of Dr. Post. Was run over by an express-wagon, and on entrance was found to have a hematoma over the left frontal eminence, beside a lacerated wound of left ear and contusion of left shoulder. The wound of the ear was dressed antiseptically. At no time were there any head or nervous symptoms. The patient was discharged on the twelfth day, apparently in excellent condition.

*Urine.* — The urine, obtained nine and half hours after the injury, was found to have a specific gravity of 1.025; albumin, the slightest possible trace; sugar, 2.92 per cent. Fermentation by yeast was very active. Two days later the urine had a specific gravity of 1.035; albumin, slightest possible trace; sugar, a very faint trace. A specimen obtained on the fifth day after the injury showed a complete disappearance of the sugar. Repeated examinations of the urine while the patient remained in the hospital, failed to show any trace of sugar after the fifth day.

CASE 52, CLASS 1. J. O'B., male, age forty-seven, janitor. Service of Dr. Watson. The patient, while intoxicated, fell from a roof, a distance of ten feet, sustaining a scalp wound one and a half inches long, running transversely between the left parietal eminence and the median line. Several contusions about the left shoulder and right side. The pupils were equal and reacted to light. Mental state dubious, because of the alcoholic condition. Scalp wound sutured and dressed antiseptically. The following day the mental condition was good, and he was feeling very well except for lameness resulting from the fall. The patient was discharged well on the seventh day.

*Urine.* — The urine which was passed about eighteen hours after the injury had a trace of sugar, this being the only time that it was found. Three months after the injury a specimen of urine was obtained from the patient and found to contain no sugar.

CASE 73, Class 1. P. F., age twenty, female. Service of Dr. Gavin. Was confined in November. 1894. While suffering from puerperal mania, which developed fifteen days later, she jumped from a third-story window (thirty feet) striking on the ground. She was brought to the hospital suffering from an incised wound of left super-orbital ridge, three-quarters of an inch in length, bone not exposed. Also on the inner aspect of the left breast a small wound one-half an inch long and a quarter of an inch deep. Milk expressed from both breasts. The wounds were dressed antiseptically. For the first few days the breasts were relieved of their secretion by means of a breast-pump. The patient remained delirious during her stay in the

hospital. The wounds entirely healed, so that she was discharged on the sixth day.

*Urine.* — On the day after entrance a trace of sugar was found in the urine. The amount of sugar increased considerably in the next few days, for on the sixth day after entrance nearly one per cent. was found. There was not only a reduction of copper in Fehling's solution, but also a noticeable fermentation with yeast.

CASE 74, CLASS 1. E. M. S., age thirty-eight, female. Service of Dr. Burrell. Was confined in March, 1894. Nine months later was struck on the head and face in a quarrel with her husband. On examination she was found to have a large hematoma over the left parietal and frontal eminences and extending down onto the left cheek. There was marked swelling of nose and about the left eye, sufficient to close it. A small contused wound behind left ear, also on left cheek. The arms, legs and lower part of trunk were covered with small excoriations and bruises. There was also a fracture of the second phalanx of the right ring-finger. There was no paralysis or head symptoms. As the patient had been nursing her child up to the time of entrance to the hospital, the breasts required massage during the first twenty-four hours only, there being no trouble afterward.

*Urine.* — The first specimen of urine, obtained about twelve hours after entrance, was found to have a specific gravity of 1.018, a large trace of albumin, and to contain a slight trace of sugar. After forty-eight hours the sugar had increased to a distinct trace, yet too slight to be quantitated, the urine having a specific gravity of 1.026, and containing a very slight trace of albumin. There was a definite fermentative reaction obtained by yeast. An examination of the urine made ten days after entrance showed a specific gravity of 1.023, a very slight trace of albumin and a complete disappearance of the sugar. Repeated examination, made later, failed to show the presence of sugar.

(Patient still in hospital, at the time of writing.)

In the consideration of these last two cases, we are confronted by the question, Have we to do with a lactosuria or a temporary glycosuria as a result of injury to the head and a general "shaking up"? In both cases, each was nursing a young child up to the time of injury, and according to Ord,[21] lactose appears in the blood during lactation. Blot,[22] de Sinetz,[23] Hoffmeister,[24] Kaltenbach,[25] Halliburton[26] and Hammersten,[27] say that lactose appears in the urine, as such, although Ord,[21] Moritz[28] and Voit[29] seem to have found it appearing in the urine as glucose, yet Moritz[30] later asserts the probability of a lactosuria.

In distinguishing between glucose and lactose we find that, according to Hammerstein, the latter is not fermentable with pure yeast, yet both reduce copper. If then, this be true, although the non-fermentation of lactose is disputed by Halliburton, we may have to do, in these two cases, with a glycosuria, either alone or coincident with a lactosuria.

### CLASS II.

CASE 87, CLASS 2. D. C., age twenty-nine, male. Service of Dr. Bolles. Fell twenty-five feet from a staging striking on right side of face, causing a wound three inches long, beneath which the malar bone, zygoma and the coronoid process of jaw were fractured. In addition, there was a small wound one inch long, with bone exposed in middle of forehead and a Colles fracture of left wrist. Patient was unconscious, remaining so several hours, following which was delirium lasting most of the time till death; pupils reacting, but unequal; no paralysis. In dressing, a number of small pieces of bone from the face were removed. The wounds healed almost throughout by primary union. On the sixth day a right facial paralysis was first noticed, with mouth drawn to the left, probably due to injury of the facial nerves. At night on the same day, patient had difficulty in swallowing, and on the next day developed a pronounced tetanus in the facial muscles, with spasm of the tongue. Following this he failed rapidly and died on the eighth day.

*Autopsy.* — Brain normal, with dura adherent to the bone at the base. No fracture about the head except in the bones of the face. Right kidney was ruptured, with hemorrhage into the suprarenal capsule. There was also hemorrhage into the capsule of the liver, on right lobe under surface. There was an acute splenic tumor, congestion of lungs, and a few small patches of sclerosis in aorta and coronary arteries.

*Urine.* — An examination of the urine passed about twelve hours after the accident, disclosed the presence of 1.04 per cent. of sugar, with a specific gravity of 1.020 and a large trace of albumin. Repeated daily examinations of the urine gave a smaller percentage of sugar each day up to the sixth, when it had entirely disappeared. A positive test by fermentation.

As on the sixth day the first symptoms of tetanus appeared, it is perfectly evident that the glycosuria could not have been caused by this complication. To which of the other lesions it was due it is impossible to determine.

CASE 112, CLASS 2. J. M., male, age fifty. Service of Dr. Monks. Five days before, fell in getting off a moving electric-car, striking head on a post. At time of entrance, on patient's head were two irregular, suppurating cavities in scalp, the first over vertex about one by one and a half inches; the second over left parietal eminence, about one-half by two inches, appearing as if the flesh had been torn away, leaving the bone uninjured, exposed beneath. In six days erysipelas of the face and scalp developed, following a chill, headache and a rise in temperature the day before. Patient did well until the twenty-second day, when without apparent cause he suddenly became unconscious and died.

*Autopsy.* — There was no evidence of fracture of the skull; great excess of serous fluid in the subarachnoid spaces and in the ventricles. The veins of the brain were distended with dark fluid blood. The puncta cruata were prominent; no meningitis. Brain substance firm, and on section no evidences of hemorrhage or pathological changes. Other organs of the body normal, except for a moderate edema and congestion of the lungs.

*Urine.* — The urine of this patient, from the time of entrance till his death, was examined frequently, and at all times was found to be above 1.030 in specific gravity and to contain a large amount of sugar, the greatest amount at any one time being 5.55 per cent. varying between that and four per cent. There was active fermentation at each examination.

As the erysipelas developed on the sixth day, it may at once be excluded in considering the cause of the glycosuria. It is possible, in view of the early presence of a large quantity of sugar in the urine, continuing

undiminished several weeks till death, that we have to do in this case with a diabetes existing prior to the injury. The previous history of the patient with respect to thirst, frequent micturition, etc., is, however, entirely negative. Charcot says that cases of persistent glycosuria following blows on the occiput are more common than, and are apt to be mistaken for, cases of true diabetes. It seems probable, then, that this may be a case of that kind.

CASE 119, CLASS 2. M. R., male, age fifty-three. Service of Dr. Cheever. Knocked down by a team in the street, causing over occiput an irregular lacerated wound three inches long, bone exposed. In addition, there was a fracture of one rib. Patient was very restless, with a mild delirium at times for several days. The wound united well by primary union, and on the twelfth day he was removed from the hospital.

*Urine.* — The first urine examined was passed ten hours after the injury. At that time the specific gravity was 1.033, with a trace of albumin and 3.84 per cent. of sugar. Two days later there was four per cent. of sugar present, with a specific gravity of 1.043. From this time on until the patient's discharge the sugar gradually decreased to 1.91 per cent. at the last examination on the twelfth day. There was a pronounced yeast fermentation at all times.

CASE 122, CLASS 2. G. A., male, age eleven. Service of Dr. Burrell. While crossing the railroad track was struck by a locomotive, causing a large hematoma over occiput, with a scalp wound two and a half inches long, bone exposed beneath. In addition, there was a compound fracture of the right leg and a bad crush of right arm necessitating amputation above the elbow. The boy suffered from profound shock, remaining unconscious for about twenty-four hours, followed by delirium lasting four to five days. He is now making an excellent recovery, still remaining in the hospital.

*Urine.* — The first urine was passed twelve hours after the injury. It contained a trace of albumin, a very small percentage of sugar, and had a specific gravity of 1.028. On the third day the trace of sugar had disappeared, and frequent examinations up to the present time have not detected its presence again.

### CLASS III.

CASE 147, CLASS 3. J. S., male, age twelve. Service of Dr. Gavin. Was thrown from a carriage in a "runaway" accident, striking on his head. He was picked up unconscious, remaining in this condition for about two hours. On arrival at the hospital, there was found a hematoma over the right parietal and occipital regions. No depression or fracture of the bones could be made out. Pupils were equal and reacted to light. He complained of slight pain in the head, this, however, being the only subjective symptom. The patient was discharged relieved on the eleventh day, in a very good general condition.

*Urine.* — The urine was unfortunately not examined for thirty-six hours, at which time 1.2 per cent. of sugar was found. On the fourth day after injury it was found that the sugar in the urine had diminished to 0.3 per cent.; on the sixth day only a faint trace; and a complete disappearance on and after the ninth day. At each examination of the urine the fermentation test with yeast was tried with a satisfactory reaction as long as the sugar remained. At no time were we able to get a reaction for acetone or diacetic acid. On the thirty-seventh day after the injury another specimen of urine was obtained from the patient, and was found to be free from sugar.

### CLASS IV.

CASE 169, CLASS 4. W. M., male, age forty. Service of Dr. Gavin. Shot himself in the head during a fit of melancholia. The patient was brought to the hospital in a semi-conscious condition, having a perforating wound one and one-half inches above and same distance back of the right ear. The pupils were equal and reacted to light; no paralysis. The wound was probed by Dr. Gavin, who found an opening having jagged edges through the skull. An effort to find the bullet was unsuccessful. Two days later the patient regained consciousness, and at this time slight paralysis on the left side, with deviation of the eyes to the right was noticed. On the fifth day became delirious and noisy, this continuing for four days. There was retention of urine on the tenth day, and at this time there was a sero-purulent discharge from the right ear. The patient's mental condition had improved somewhat, and the general condition remained pretty good to the twenty-eighth day, when he became unconscious; the retention of urine had given way to incontinence, still paralysis of left side. Death occurred on the twenty-ninth day.

*Autopsy.* — A well-marked cicatrix situated two inches behind and one and one-half inches above external angular process. On removing the scalp a circular opening through skull was found. A fracture one-half inch behind coronal suture, penetrating the great wing of the sphenoid bone. Bullet was found just inside the opening in the skull and over the third frontal convolution just anterior to the ascending limb of Sylvius. This frontal convolution was softened and destroyed. There was no abscess cavity at this point.

*Urine.* — An examination of the urine, made seventeen hours after the injury, had a specific gravity of 1.025; albumin, slightest possible trace; sugar, a trace, too slight to be quantitated. Repeated examinations were made during the life of the patient, but no sugar was found at any time after the first examination.

CASE 191, CLASS 4. G. M. R., male, age fourteen. Service of Dr. Watson. Was struck on the head by the shaft of a planing-machine, sustaining a lacerated wound extending from the bridge of nose to supraorbital ridge of frontal, destroying left eye, and involving the nasal, frontal, malar, and possibly superior maxillary bones in compound comminuted fracture. On entrance to the hospital was conscious, pulse rapid but of low tension. The patient was operated upon by Dr Monks, who enucleated all remains of the eye, removed fragments of bone, thoroughly cleansed and dressed the wound antiseptically. The next day, while dressing the wound, a rather profuse discharge of sero-sanguinous matter was observed. There followed a good recovery, and he was discharged on the nineteenth day.

*Urine.* — An examination of the urine, twenty-four hours after the injury, showed specific gravity of 1.035, slightest possible trace of albumin, 0.85 per cent. of sugar. The fermentation test was active. During the patient's stay in the hospital, unfortunately the urine was not examined again; but five months after the injury the patient returned for observation, and

the urine was found to have a specific gravity of 1.020, slight trace of albumin, and contained no sugar.

Case 180, Class 4. M. K., female, age fifty-two. Service of Dr. Bolles. In an encounter with a burglar was struck twice on the head with an unknown implement. She remained in an unconscious condition about four and a half hours. On entrance, the patient was found to be a fleshy woman with a scalp wound about three inches in length over the right frontal eminence, and a crack in the bone running forward. No depression of bone. The wound was treated antiseptically. No pre-existing history or symptoms of diabetes in patient or in ancestors. An uninterrupted recovery followed, without any notable subjective symptoms. The patient was discharged on the nineteenth day.

*Urine.* — Eighteen hours after entrance, specific gravity 1.040; albumin, very slight trace; sugar present (not quantitated). The amount of urine passed in the first twenty-four hours was 1,080 c. c.

Third day, amount, 960 c. c.; specific gravity 1.037; albumin, very slight trace; sugar, 2.5 per cent. Marked fermentative reaction.

Fourth day, amount, 1,260 c. c.; specific gravity 1.024; albumin as before; sugar, 1.19 per cent. Marked fermentative reaction.

Seventh day, amount 1,500 c. c.; specific gravity 1.016; albumin as before; sugar, 0.35 per cent. Very slight fermentation.

Ninth day, amount, 1,800 c. c.; specific gravity 1.016; albumin as before; sugar present, but too slight to quantitate. No fermentative reaction.

Eleventh day, amount, 1,380 c. c.; specific gravity 1.028; albumin, a slight trace; sugar, a trace, too slight to quantitate.

Twelfth day, amount, 1,830 c. c.; specific gravity 1.030; albumin, a very slight trace; sugar, 3.84 per cent. Fermentation very active.

Thirteenth day, amount, 1,260 c. c.; specific gravity 1.042; albumin as before; sugar, 4.16 per cent. Fermentation very active.

Fifteenth day, amount, 650 c. c.; specific gravity 1.042; albumin as before; sugar, 5.43 per cent. Fermentation very active.

Sixteenth day, amount, accidentally lost; specific gravity 1.036; albumin as before; sugar, 2.38 per cent. Fermentation active.

Nineteenth day, amount, 1,350 c. c.; specific gravity 1.033; albumin, very slight trace; sugar, 1.29 per cent. Fermentation active. Discharged on this day.

Acetone and diacetic acid were not obtained at any time, although tested for at each examination of the urine.

There are some points in this case which would tend to show a pre-existing permanent diabetes, namely, a corpulent individual, the continued presence and invariable large percentage of sugar. On the other hand, we could get no history of diabetes (pruritis, excessive thirst, a noticeable increase in the daily amount of urine, etc.). The daily amount of urine while in the hospital, was generally below 1,500 c. c. (although this might well be in a case of permanent diabetes).

Case 181, Class 4. F. R., male, age nineteen. Service of Dr. Bolles. During a quarrel he was struck on the head with an iron bar about an inch in diameter. His mind was perfectly clear after the accident. On entering the hospital, there was found a scalp wound about three inches in length over the right temporal bone, with an exposure and depression of bone. The depression extended over an area of about half an inch and about one-eighth of an inch in depth. There were no subjective symptoms except for rather severe headache. The temporal bone was trephined, and several small pieces of bone removed. No subjective symptoms. A good recovery followed, and he was discharged on the nineteenth day.

*Urine.* — At the first examination, made three days after injury, there was a specific gravity of 1.028, and no sugar or albumin present. On the sixth day the urine had a specific gravity of 1.030 and a very slight trace of albumin and sugar. There was a complete disappearance of the sugar two days later, and no recurrence during his stay at the hospital.

Case 183, Class 4. J. R., male, age twenty-four. Service of Dr. Bolles. Was struck on the head by a large piece of coal which fell from a staging above. He was knocked down, and was insensible for only a few moments. He then walked home without assistance. Three hours and a half later he became unconscious, and was brought to the hospital in this condition. Examination showed a well-developed man. Pulse rapid (160); respiration 40, and simulating the Cheyne-Stokes character. Both pupils dilated; left more than right, and reacting sluggishly to light. A small scalp wound at the coronal suture, in the median line. All extremities were rigid, relaxing momentarily at times. The operation of trephining was performed by Dr. Bolles, who removed a button at the point of scalp wound and another one over the course of the left middle meningeal artery, but nothing was found in either place to account for the symptoms. Death occurred fifteen hours after the injury. There was no autopsy.

*Urine.* — About eight hours after the injury, the urine was drawn by catheter, and found to have a specific gravity of 1.033; albumin, a very slight trace; sugar, a faint trace (too slight to quantitate). Only one examination was made before death.

### Class V.

Case 212, Class 5. C. A. L., age forty-two, male. Service of Dr. Watson. Was thrown out of carriage one-half hour before entrance. When seen first, there was slight stupor, from which he could be aroused sufficiently to give name and age, but relapsed immediately on being allowed to remain undisturbed, and at the end of another hour was totally unconscious, soon becoming delirious. Over right parietal region was a large swelling beneath which nothing could be felt; hemorrhage from left ear; no paralysis, knee-jerks slightly increased, examination otherwise negative. About three hours after the accident an incision was made over swelling, revealing a crack in the bone, running downwards and forwards towards the base. Bone was trephined, finding the dura lacerated with considerable hemorrhage, necessitating tying the posterior branch of the middle meningeal artery. Patient did not recover consciousness after the operation. He continued noisy and delirious, dying forty-five hours after the accident.

*Urine.* — It was possible to obtain only one specimen of urine from the patient. A small quantity was drawn by catheter sixteen hours after the injury. At that time it contained a very slight trace of albumin, with a specific gravity of 1.030; and a trace of sugar was found by Fehling's and the fermentation tests.

CASE 201, CLASS 5. J. S., age thirty-seven, male. Service of Dr. Bolles. Twenty-four hours before entrance fell into the hold of a vessel, striking on head. At entrance unconscious, very restless and delirious; no paralysis. Over occiput, a scalp wound three inches long, bone exposed beneath, in which a fracture was found extending into base beyond limits of wound. No depression or fissure. There was a bloody serous discharge from right ear, also a slight exophthalmos of right eye. Patient continued delirious, and died thirty-four hours after the injury. No autopsy.

*Urine.* — Catheter specimen was obtained twenty hours after fall. Specific gravity was 1.027, containing a trace of albumin, and sugar to 1.25 per cent. This was the only examination made.

CASE 208, CLASS 5. G. L., age twenty three, male. Service of Dr. Bradford. Shortly before entrance fell twenty feet, striking on frozen ground. No external signs of violence; paralysis of right arm and leg. Unconscious, delirious, and very restless, lasting for about six days without other special subjective symptoms. Patient then made gradual improvement mentally and in the use of right arm and leg; and on the twenty-ninth day, being up and walking about, was discharged.

*Urine.* — On the third day after the injury, the urine was found to contain a very small amount of sugar with a slight trace of albumin, and a specific gravity of 1.030. This was the only time that sugar was found present.

CASE 193, CLASS 5. C. H. C., age fifty-four, male. Service of Dr. Monks. On the morning of entrance patient was struck on the head by a piece of falling machinery; was brought to the hospital unconscious, cyanotic; no paralysis; respiration slow and stertorous; pupils fixed, and there was slight external strabismus of both eyes. Over right parietal and temporal regions was a large hematoma, beneath which nothing could be distinguished. There was no hemorrhage from ears, nose or mouth. An immediate operation was performed; on removing the flap over an area two inches in diameter, the bone was found comminuted and depressed, with line of fracture extending into nose. Beneath, the dura was badly lacerated. Between the bone and dura was a large clot from the middle meningeal, which was ligated. Fragments of bone and the clot were removed, and the wound closed and drained. Patient failed rapidly, dying nine hours after the injury. No autopsy.

*Urine.* — The only specimen of urine obtained was drawn by catheter about six hours after the accident, immediately before operation. It had a specific gravity of 1.022, the slightest possible trace of albumin, and 2.17 per cent. of sugar.

CASE 196, CLASS 5. T. O'C., age twenty-seven, male. Service of Dr. Monks. Twenty hours before entrance to hospital was assaulted in an unknown manner. Patient was unconscious, very restless and delirious, with no marks of injury about head. There was evidence of old hemorrhage from left ear, but otherwise physical examination was negative. Death occurred about thirty hours after injury.

*Autopsy.* — Over left occipito-parietal region there was considerable infiltration of the scalp over an area four inches in diameter. Skull was fractured, beginning at about one inch to the left of the junction of the occipital and two parietal bones and extending to the left, downwards and forwards, across parietal and temporal bones, through the petrous, and stopping near the middle of squamous portion. There was no fissure or depression. Surface of brain vessels markedly injected with little free blood within arachnoid spaces. At the base pia moist and opaque, covered with a thick exudation of pus and serum. To a less degree, some exudation found along sulci from base to vertex. Base of frontal lobes bruised over an area one inch in diameter and one-quarter inch deep, also slight bruising at tip of left temporal lobe. Substance of brain moist and soft. Kidneys slightly enlarged, injected and granular. Organs otherwise normal.

*Anatomical Diagnosis.* — Fracture base of skull, contusion of brain and purulent meningitis.

*Urine.* — A catheter specimen was obtained immediately after entrance, twenty hours after the injury. The specific gravity was 1.030; it had a large trace of albumin, and sugar was present to less than one per cent., too small to determine quantitatively.

RESULTS.

Total number of cases examined 212; cases of glycosuria 20, or 9.43 per cent.
Class I. Number of cases 84; glycosuria 5, or 5.95 per cent.
Class II. Number of cases 43; glycosuria 4, or 9.3 per cent.
Class III. Number of cases 40; glycosuria 1, or 2.5 per cent.
Class IV. Number of cases 24; glycosuria 5, or 20.8 per cent.
Class V. Number of cases 21; glycosuria 5, or 23.8 per cent.

These figures show the results obtained in percentages of cases having sugar, taken both collectively and as they have been arranged in classes.

Assuming that of all the twenty cases which had glycosuria, none were diabetic before the injury, there is then a percentage of 9.43 in general for all classes of head injuries. This is fully as high as could be expected, considering the large proportion of the whole number of cases (167 out of 212) in Classes 1, 2 and 3. These would generally be considered as minor accidents.

It does not seem unfair to argue upon the assumption that in all the patients the glycosuria occurred as the result of the trauma and that they were not diabetic before. This seems especially reasonable when the fact is taken into consideration that of 1,563 patients, the whole number of accident cases admitted to the hospital for the same thirteen months during which the head cases have been studied, no case apart from those with head injuries was found to have glycosuria. As it is, there are only three cases out of the whole number — J. M., Case 112, Class 2; M. R., Case 119, Class 2; and M. K., Case 180, Class 4 — in which there can be any question. From a careful study of these after the accidents and taking into consideration their previous histories, it seems very probable that a permanent glycosuria was consequent upon the head injury, rather than that a diabetes existed previously.

With the exception of Class 3, which shows a surprisingly small percentage of sugar cases, there is considerable increase in the number with each higher class. This is, as would naturally be expected, very noticeable in the increase of the last two over the preceding one. The difference between these two considered together, apart from the other classes, is not sufficient to be of any marked significance. It has been of considerable interest, however, to consider them separately in this paper.

In general, then, it can be said that all classes of head injuries taken together, about 10 per cent. mani-

fest glycosuria as the result of traumatism, while the severe cases, fractures both of the vertex and base, from 20 per cent. to 25 per cent. have glycosuria.

Sugar may be present in the urine following any head injuries, however slight. It is present much more frequently following severe injuries. From a diagnostic standpoint it is difficult to see how the presence of a glycosuria can render any assistance.

### INJURIES TO THE SPINE AND BACK.

During the period over which our observations have extended, a limited number of cases of injury to the spine and back have been followed, but intentionally left out of the tables. According to Vogel,[31] Warren,[32] Ebstein[33] and others, transitory glycosuria, but more often permanent diabetes, may follow such injuries, and is considered by most of the above observers to be due to concussion of the spine. Of such cases seen in the hospital during the thirteen months, none presented sugar in the urine, although carefully sought for.

### EXAMINATION OF THE URINE.

The greatest care has been used in the examination of the urine of all cases, and in each especial reference made to the test for sugar.

Fehling's solution was used for both the qualitative and quantitative tests. The routine qualitative tests were made as follows: Taking about three to five cubic centimetres of a freshly prepared Fehling's solution, boiling, and then adding five to fifteen drops of the urine, from which the albumin (if more than a very slight trace) had been previously removed. The solution was *not* boiled after the addition of the urine, but immediately set aside and carefully watched for a reduction. If no reduction of the copper appeared within an hour or two, it was set aside for twenty-four hours and again examined for a deposit of the suboxide of copper. The amounts of sugar which have been designated as a trace and a very slight trace, appeared only after twenty-four hours, and in every instance a distinct precipitate of the suboxide of copper was found. No effort to quantitate slight traces of sugar was undertaken, for such would have been useless. In every case, however, where the amount of sugar was sufficient, a quantitative test was made.

In most of the sugar cases the fermentation test was made, not as a means of quantitation, but to detect the presence of glucose; and in all cases in which it was used it proved confirmatory.

Albumin, together with casts and abnormal blood, was found in every case containing sugar, probably secondary, in most instances, to the renal irritation produced by the sugar, even though it had been eliminated only a short time.

Since acetone and diacetic acid are a frequent accompaniment of sugar in the urine, especially in the permanent forms of diabetes, it is of interest to note that they were not found in any of the sugar cases here recorded.

Ebstein[33] reports a case in whose urine acetone and diacetic acid were found, not until eight years after an injury, resulting in a permanent diabetes. As far as found, there is no literature bearing on this subject in those cases where sugar follows a head injury immediately or in a few days. It would appear, then — in cases J. M., Case 112, Class 2; M. R., Case 119, Class 2; and M. K., Case 180, Class 4, where there is some question as to a permanent pre-existing diabetes — that a point in favor of a permanent glycosuria following the injury is the absence of acetone and diacetic acid.

### AGE AND SEX.

The ages of the cases, where sugar was found, varies between four and a half and fifty-four years, and are quite evenly distributed between these limits. It is therefore concluded from such cases as here observed, that the age has no practical significance.

As regards the sex, very little of value can be drawn. Although 85 per cent. of the cases having sugar were males, yet it appears to be relative, much more, to the liability to injury (as among manual laborers) than to the sex alone.

### DIET.

From the fact that the diet is oftentimes an important factor in the appearance and disappearance of sugar in the urine, it might be well to state, in a few words, that it had little or no attention in those cases where sugar was found. Following the injury, the patient had milk in sufficient quantities, until the general condition warranted a more generous and substantial diet of meat, vegetables, etc. It is therefore obvious that this question has practically no weight in the sugar cases considered.

### CONCLUSIONS.

(1) That, after injury, sugar may appear in the urine as early as six hours, and disappear within twenty-four, the average time for its appearance, however, being from eight to twelve hours; for the disappearance of the same, from the fifth to the ninth day.

(2) That a small proportion of the cases may exhibit a permanent glycosuria from the date of injury to the head.

(3) That acetone and diacetic acid are rarely if ever found in such cases, excepting where the condition becomes a permanent glycosuria, and even then probably only after a number of months or years.

(4) That of the twenty sugar cases here recorded, eleven (55 per cent.) had received an injury to the right side of the head; five (25 per cent.) to the left side; three (15 per cent.) to the occiput, and two (10 per cent.) where there was no external evidences of violence.

(5) That it is impossible in the present state of the knowledge of the pathology of diabetes and glycosuria to draw any inferences from the autopsies which have been obtained. It was thought best, however, to report them in full.

(6) That there is little to be said in regard to the mortality. Of the twenty cases, eight died — six being the direct result of severe injuries, one from intercurrent disease, and the third probably from alcoholism. In the 212 cases, 16 were fatal, 50 per cent. of these having glycosuria.

## THE TREATMENT OF CHOREA, WITH ESPECIAL REFERENCE TO THE USE OF QUININE.[1]

BY PHILIP COOMBS KNAPP, A.M., M.D.,
*Clinical Instructor in Diseases of the Nervous System, Harvard Medical School; Physician for Diseases of the Nervous System, Boston City Hospital.*

IN January, 1893, as the result of a conversation with Dr. H. C. Wood of Philadelphia, I was led to try the effects of quinine in the treatment of chorea, during my service at the City Hospital. Quinine was given in eleven cases, but three of these failed to report regularly, so that they will not be considered.

In addition to the quinine the ordinary hygienic measures and regimen such as I ordinarily recommend in the treatment of chorea were employed. The children were ordered to be taken out of school, cold sponge baths were given daily, the diet was regulated and forced feeding was prescribed, the amount of out-of-door exercise was strictly limited, and as much rest as practicable was enjoined. No other medicinal treatment was given, not even cod liver oil or any malt preparations. Quinine was given in doses of from six to eighteen grains a day, the doses being rather smaller than those given by Dr. Wood, as at that time I did not know that he advised pushing quinine until cinchonism was obtained.

The results in the eight cases were as follows, details as to the clinical history being omitted:

CASE I. R. H., age twenty, single, a cigar-maker, came to the hospital on the 24th of February, 1893. She was a Jewess. Her mother had been under treatment at the hospital for rheumatism, and her younger sister had been to the out-patient department the previous year, suffering from a third attack of chorea. For three weeks she had had choreic movements of the left arm and face; the movements being marked. There were no heart murmurs and she had never had rheumatism. She was given five grains of quinine three times a day.

On the 27th she reported that she had had severe headache, and had been unable to sleep. She had also been extremely emotional and hysterical, and the movements were more marked. The quinine was given only once a day.

On the 1st of March she was much better. She slept well and had no headache. The choreic movements could hardly be detected. She was given two and a half grains of quinine three times a day.

On the 3d no chorea could be detected, and she was much better. She was discharged with orders to report should there be any return of the trouble; but she remained well.

CASE II. Patrick M., ten years old, a school-boy of Irish parentage, came to the hospital on the 5th of May, 1893. He had had acute articular rheumatism all winter, and for four days he had had severe and general choreic movements. There was no cardiac trouble. He was given two grains of quinine four times a day.

On the 12th he was much better. The quinine was increased to four grains.

On the 22d the chorea had ceased, and all treatment was discontinued.

On the 26th he was discharged, well.

CASE III. Mary S., age thirteen, a school-girl of Irish parentage, came to the hospital on the 20th of March, 1893. She had had general chorea, worse on the right side, for two weeks, the movements being well marked. She had never had rheumatism and had no cardiac complications. She was given two grains of quinine three times a day.

On the 24th the movements were diminished. The quinine was increased to four grains.

She improved gradually, but on the 24th of April there was still some twitching. The quinine was increased to six grains.

She gained slowly and was discharged well on the 31st of May.

CASE IV. Addie L., age nineteen, single, a Jewess, came to the hospital on the 31st of March, 1893. There was a history of rheumatism in the family. She had had chorea and neurasthenia previously. For two weeks she had had general choreic movements, worse on the right side. She had never had rheumatism, and the heart was not affected. She was given two grains of quinine three times a day.

On the 3d of April she complained of more headache, but she slept better. The twitching was not changed.

On the 19th she was a trifle better, but she had been distinctly worse. The quinine was discontinued by my assistant, Dr. Burr, and she was given arsenic. She continued to improve, but discontinued treatment in May, before she was entirely well.

CASE V. Maud M., age nine, a school-girl, came to the hospital on the 17th of April, 1893. For ten days she had had marked choreic movements on the left side. She had never had rheumatism. There was some reduplication of the first sound of the heart at the apex, but no murmur. She was given two grains of quinine four times a day.

On the 21st the movements were worse and the quinine was increased to four grains.

[1] Read before the Boston Society for Medical Observation, December 3, 1894.

On the 1st of May she was still worse, the quinine was discontinued and arsenic ordered.

She improved steadily, and when last seen, on the 22d of May, just before I went off duty, she was nearly well.

Case VI. James M., age twelve, a school-boy of Irish parentage, came to the hospital on the 15th of March, 1893. He had been irritable, and unable to write at school for a month, and for a week he had had marked chorea on the left side. There was no cardiac murmur and no rheumatism. He was given two grains of quinine three times a day.

On the 17th the choreic movements were worse, but he slept a little better. The quinine was given four times a day.

On the 20th the twitching had increased. The quinine was increased to four grains three times a day.

On the 27th he had improved a trifle. The quinine was increased to six grains.

On the 31st he was much worse, and the twitching had extended to the right hand. The quinine was discontinued, and arsenic and iron given. From this time he continued to improve, and on the 28th of April was well.

Case VII. Ellen D., age thirteen, a school-girl of Irish parentage, came to the hospital on the 28th of April, 1893. She had had marked choreic movements on the left side for three days. She had never had rheumatism; the heart was somewhat tumultuous, but there were no murmurs. She was given two grains of quinine three times a day.

On the 19th of May, there being no improvement in her condition, the quinine was discontinued, and arsenic was given, under which she improved during the week she remained under observation.

Case VIII. John D., age thirteen, a school-boy, came to the hospital on the 3d of May, 1893. He had had acute articular rheumatism during the winter. For four weeks he had had choreic movements on the right side. The heart was normal. He was given two grains of quinine three times a day.

On the 5th his condition was unchanged. The quinine was increased to four grains.

On the 8th there was still no change. The quinine was increased to six grains.

On the 12th he was worse. The quinine was discontinued, and arsenic given. Under this he improved slowly during the fortnight he remained under observation.

To sum up: in one case there was complete recovery in a week after treatment was begun, and in a second in three weeks, but, although this is rather a short time, it is not very remarkable for chorea to recover in that period. The third case recovered after being under treatment ten weeks. In five cases the quinine treatment proved ineffectual and arsenic was substituted, with distinct benefit in the majority of cases. With the exception of Case I, which recovered in a week, the results are neither remarkable nor satisfactory.

During this period Dr. Wood had published [1] the results of experiments on animals and had been putting his hypothesis into practice, reporting his results [2] at a meeting of the Association of American Physicians in May, 1893.

[1] H. C. Wood: Choreic Movement, Journal of Nervous and Mental Disease, April, 1893.

[2] H. C. Wood: Note on Use of Quinine in Chorea, Transactions Association of American Physicians, viii, 101, 1893.

In studying canine chorea Dr. Wood, in common with other observers, found that the movements continued after section of the spinal cord. He therefore concludes that the seat of the morbid process in chorea is in the cord. Although in chorea the motor function of the cord is somewhat impaired, he holds that the inhibitory motor function is still more impaired; that Setschenow's centres are too weak to arrest the voluntary movement as soon as its end is attained, and that in consequence the movement goes beyond the normal limits. Atropine paralyses the inhibitory function of the cord, and quinine stimulates it, and, in the first paper cited, he showed that the choreic movements in the dog were enormously increased by atropine, and completely checked by quinine.

In the second paper he gives the application of these theories. In six cases of canine chorea he gave quinine, with the result that in every case the movements were inhibited, and that in four cases the dogs recovered — canine chorea being usually a fatal disease. In two cases of chorea in children he gave quinine in doses of nine to twenty-four grains daily for seven and a half weeks, one case recovering, and one case being greatly improved. He reported eleven other cases communicated to him by others. In nine cases (in two of which arsenic had failed) the patients recovered in from three to fifteen days, after taking nine to twenty-five grains of quinine daily. In two cases quinine failed and arsenic was substituted; one of these cases did not improve at all, the other recovered.

These results are more satisfactory than my own, but they are hardly conclusive. I believe that in a certain number of cases of chorea very good results might be obtained by removing the child from the bad hygienic surroundings in which it lives, by giving a liberal and nourishing diet, instead of the tea, candy, and bread on which so many of them feed, by enforcing as absolute rest in bed as can be attained, and by judicious hydrotherapy, without the aid of drugs. Nevertheless, we cannot regard chorea as a self-limited disease, in spite of the recent theories as to its nature to which I shall presently refer, for in only too many cases the trouble is protracted and may even became chronic. I have never yet ventured to try a purely expectant treatment, and I fully believe that in many cases the attack is much relieved and shortened by the ordinary drugs in use, notably, of course, arsenic.

The ordinary methods of treatment will in many simple cases be followed by complete or nearly complete recovery in from four to ten weeks, and therefore the results in a part of these cases treated by quinine are no better than the results in other cases. I must admit that I have not seen recovery under other forms of treatment inside of a week, so that the cases collected by Dr. Wood are of more weight in supporting his theory than his own cases or mine.

I do not believe, however, that the use of quinine in chorea can be justified on the hypothesis of its action in stimulating the inhibitory motor functions of the spinal cord. That quinine may be of benefit as a tonic is of course evident, and it may have some influence upon the toxine that produces chorea. Chorea, however, cannot be regarded as a spinal disease. The pronounced cerebral symptoms, insomnia, irritability, headache, mental failure, and the distribution of the choreic movements, which are so often found to affect one side or even one limb predominantly, would of

themselves point to the cerebral origin of the disease, even without the evidence afforded by autopsies, which have shown the most marked changes in the cerebral cortex, although the basal ganglia and the cord itself have not been exempt. Choreic movements are not uncommon as a result of structural brain disease, but they are rarely if ever seen as a symptom of diseases of the cord. In canine chorea, on the other hand, which is not proven to be the same as human chorea, the changes are chiefly in the cord. It is possible that in some cases, such as those reported to the American Neurological Association in 1890 by Weir Mitchell, the morbid process may affect chiefly the cord, but such cases are rare.

It is furthermore possible that in the future we may differentiate several affections which are now called chorea. Huntington's chorea and the electric chorea of Dubini are now fully recognized as distinct diseases, having no connection with the ordinary chorea of childhood — Sydenham's chorea. Evidence is accumulating that in most cases of Sydenham's chorea we have to do with a disease of microbic origin, and the researches of Berkeley, Dana and Pianese have done much to confirm that belief. Other cases, including some of the rather rare cases which are alleged to be due to fright or to irritation, may be of hysterical origin. In chorea of microbic origin the toxine probably exerts its chief influence upon the brain cortex, especially in its motor region.

The hypothesis on which quinine is recommended for the treatment of chorea seems to me untenable, and the therapeutic results are based thus far on too few cases to warrant us in ascribing greater virtues to this drug than to arsenic. Not having the idea at the time of publishing the results of this very imperfect trial of the drug, the results of one season's trial did not seem to me of sufficient value to lead me to try it in my private practice or in my subsequent terms of service at the hospital, and I went back to my former custom of supplementing the rest and regimen with full doses of arsenic, associated if necessary with iron or other tonics, and, in case of great motor disturbance and restlessness, with sulfonal or other sedatives.

## INTESTINAL INCISION AND DRAINAGE IN ACUTE PERITONITIS.[1]

BY S. J. MIXTER, M.D.

WHATEVER the starting-point of the process, or however simple and comparatively safe its treatment by early operation might have been, the presence of a more or less general peritonitis renders the prognosis a very unfavorable one. In spite of removal of the band, suppurating tube, or sloughing appendix, together with irrigation and drainage by tubes or gauze, the abdominal distension increases, the paralyzed bowel refuses to do its work, and the patient generally dies.

On opening the abdomen of a patient with such symptoms, we find the intestines distended with gas, and containing also a considerable amount of liquid feces. They are red and rough, and the peritoneal cavity contains a large amount of cloudy or purulent serum and perhaps flakes of fibrin.

The mere fact of the great distention makes any search for the primary seat of inflammation difficult and tedious, and often an almost complete evisceration is the only method by which we can make a satisfactory exploration.

It is impossible to handle the distended coils without using some force, and there is danger of tearing them or the mesentery, especially when returning them to the abdominal cavity.

An aspirator needle or small trocar may be used to draw off some of the gas, but there is always danger of leakage at the point of puncture. A free opening with the knife is much more satisfactory and thorough, and the openings are easily closed with the over-and-over stitch.

Given, then, great distention, I believe that it is safe to open the coils of intestine at as many points as may be necessary to thoroughly drain them. They should be drawn out of the wound, held over a basin, incised in one to four or five places, and thoroughly emptied. They should then be quickly washed off with hot water containing a little salt, sewed up and returned, and the operation completed.

It is astonishing what a large amount of foul-smelling liquid feces may be removed, two quarts being not an enormous amount.

So far we have considered only the mechanical reason for this procedure. There are also other reasons equally important. The bowel has a chance to contract and recover from its almost total muscular paralysis, and the danger of septic absorption from the fermenting feces is lessened. This latter is, I am sure, a great source of danger in these cases. Abbe, in his article on intestinal anastomosis, speaks of this absorption by the intestine as a frequent cause of death after operations for obstruction, and he recommends making an artificial anus, and closing it by a secondary suture of the gut. By means of free incision and evacuation, I have several times been able to succeed in these operations without the formation of an external opening.

When, however, the bowel seems to be thoroughly paralyzed, and there is reason to think that neither the stomach nor rectum will retain and absorb the necessary salts, stimulants or food, a temporary opening may be made in the cecum, especially if the external opening is in the right side, as in cases of appendicitis. This is best done by means of a curved tube with a button on the end, which is introduced through a small hole made in the most prominent part of the cecum, and tied in, so that leakage shall not occur around it, for the first twenty-four hours. This is packed about with gauze, and a rubber tube is carried from it out through the dressing. Through this tube we can draw off any gas or feces that may accumulate, and introduce our salts and stimulants with less trouble and much greater certainty than by the rectum.

It may be said against free incision of the bowel, that there is danger of subsequent leakage; but, after using this method in nearly twenty cases, I have never known it to occur. Many of the cases have recovered, and in nearly all that have died the bowel was examined after death and found to be tight.

Against drainage of the cecum, it must, of course, be said, that there is danger or probability of the formation of a permanent fecal fistula. I can only say that I have pursued this method in two cases, one of which recovered. In this case the opening has given little trouble, has been easily controlled by a pad, and

[1] Read before the Boston Society for Medical Observation, December 3, 1894.

now, some three months after the operation, is very small, and will, I think, close spontaneously; if it does not, the opening is in the wide part of the gut and directly under the scar, where it may be easily reached and closed.

In the second case, where the tube was tied into the cecum, the patient died in thirty-six hours after the operation, but with no distention. Dr. Cotton examined the abdominal cavity after death, through the wound, and reports as follows:

"Autopsy by wound (no cuts). Gauze removed. Parts in normal relation. Cecum projecting into wound; not strangulated; empty or nearly. Beyond the packing the bowels were barely dulled, and only here and there any vague suggestion of lymph. No flakes. Practically no fluid in abdomen. Lower hole of puncture tight. No adhesions. Upper hole imbedded in adherent bowel; both tight; both tight with considerable pressure applied through fluid contents. Appendix stump tight; no pus about it. Here and there, at juncture of mesentery and bowel, minute ecchymoses."

After the experience that I have had with this method, I feel sure that by it we can save certain patients that would otherwise die.

## THE STOMACH TEST IN MURDER TRIALS.

BY GUSTAV LIEBMANN, M.D., BOSTON.

The object of this test is to ascertain by the presence or absence of solid contents or by the intermediary stages of liquefaction of food found in the stomach how far the process of digestion had advanced, giving thus a clew as to the time at which death of the victim had taken place, provided the time of the last meal be known. In order to arrive at an exact, or at least approximately exact, conclusion, the first and imperative condition would be an uniformly established and acknowledged schedule of time, in which the different phases of digestion should be completed. If there be such a physiological law, from which there is practically no deviation, we should place full reliance upon the test; but if there be, in healthy people even, numerous exceptions or deviations, the test must of necessity be open to errors. Now I hold that this latter proposition is the true one. The food does not drop out of the stomach with the regularity of the shot that drops out of the cylinder in the new Connecticut hanging-machine. To be sure, in a good many cases it is disposed of in from four to five hours after eating, the time set down in the text-books as necessary for the completion of the digestive process. But, as a matter of fact, in almost quite as many other cases this term is exceeded by two to three hours; so that Leube, for instance, in order to determine the duration of digestion, never takes out the stomach contents before seven hours after the test-meal.

The different variations in the duration of the digestive process depend upon the following conditions:

(1) The length of time necessary to the transformation of solids into chyme in healthy individuals varies a great deal according to the digestibility of the different foods.

(2) The length of time necessary to expel the ingesta from the stomach into the duodenum in the healthy individual varies according to the quantities of food taken. Not only does it take a longer time for larger quantities to be impelled on, but the motor activity of the stomach walls is diminished by the greater distention produced by the larger amount of food. Thus, pieces of meat are frequently found a day or longer after eating.

(3) The shorter or longer stay of food depends on the amount of acidity, which varies in different stomachs even within the border-lines of health.

(4) Much variation, even in health, is caused by individuality, by presence or absence of pepsin, hydrochloric acid, psychical factors, emotions (fright, fear, grief, or the opposite, as joy or exaltation).

We see, therefore, that owing to the many physiological variations which do not permit of any reliable deductions even in the healthy, the forensic value of this test must be considerably impaired. To be sure, if we had a perfectly safe and reliable standard of time, at the end of which digestion is completed and during the different phases of which certain changes of a physical and chemical nature must have been wrought with the accuracy of a clock, then indeed the test would be a reliable one. But, as we have shown, we meet with so many considerable variations (in some individuals the stomach is empty four or five hours after a test-meal; in others, only after eight or more hours), that a uniform standard time for the completion of digestion is out of the question. And, if this be so within the border-line of health, how much greater must these variations be in the dyspeptic; and yet, when the test is made, is there any attention paid to the possible diseased condition of the stomach? Not to my knowledge. And yet the chances are, that by reason of an atony of the stomach walls, of a chronic glandular gastritis or of a dilatation of the viscus the food has remained far too long in the stomach, and that the examiner will fix the occurrence of death, in accordance with the tardy progress of digestion, at an entirely too early a time.

On the other hand, there are stomachs, which in case their motive functions are unduly increased, expel their contents in an exceptionally short time — to the detriment of their possessors at that. And here the possibility arises, that the test might lead us astray in the opposite direction, in that the time of death would be fixed at a later time than warranted by the facts. The stomach is found empty; therefore the time of death is put down as having occurred at least five hours after the last meal, while in point of fact the emptying of the organ might have been complete three hours after that meal. To be sure, such cases are not the rule, but they are on record, and should be reckoned with.

From the foregoing it would therefore appear that this so-called stomach test, as applied at present to determine the time of death of the victim, is not alone inexact, but that there is even a great question whether it is approximately correct.

---

Sterilization of Doctors. — It has been proposed by Gutmann that stations be erected in convenient localities in cities and large towns where physicians may go to be thoroughly disinfected immediately after they have visited a case of infectious disease, and before paying any further visits. The operation will take about fifteen minutes, and then the doctor may go about his business, proud in the consciousness of being clean and no longer a menace to the health of his fellows. — *Annals Hygiene.*

## Clinical Department.

### CALCULI OF THE KIDNEY, WITH HYDRONEPHROSIS.

BY W. H. PRESCOTT, M.D.

THE case which I wish to report is that of a woman upon whom I performed an autopsy February 15th. She was a patient at the New England Hospital for Women and Children, and I am indebted to the physicians of the hospital for the clinical history.

Mrs. C. P., age fifty-one, married, a German, was first seen by Dr. E. C. Keller in the spring of 1891, when she was suffering with an attack of severe abdominal pain, the symptoms being obscure. There was at this time a tumor on the right side, which disappeared with a great discharge of pus in the urine. She had no further trouble until her present illness.

She was admitted to the hospital January 31, 1893. On entrance, her appetite and digestion were poor; bowels irregular; insomnia; temperature 99°; pulse 112, weak and compressible; somewhat emaciated and cachectic; tongue red on tip and edges, dark pasty coating on dorsum. The amount of urine in twenty-four hours was 22 ounces, specific gravity 1.010, color pale, opaque, albumin in considerable quantity, pus corpuscles abundant.

February 1st. Physical examination showed a tumor in the right lumbar region, probably of the kidney; hemorrhoids; uterus larger than normal, with nodule in the right cul-de-sac.

February 2d. Consultation of attending surgeons. The mass outlined on the right side seemed to connect with the liver. It was sensitive, probably a pyo-nephrosis.

The patient has been losing *flesh* since November, 1892. Retains only milk. Throbbing headache and blurred vision. Occasionally abdominal pain, and tenderness on pressure, especially in the right lumbar region. Great thirst.

February 6th. Consultation with Dr. Arthur T. Cabot as to exploratory incision. The low specific gravity, absence of casts, and great thirst pointed to disease of both kidneys, and operation was contraindicated.

February 13th. Patient became worse, weaker. Retains almost nothing. Less pus in urine. Watery stools. Coffee-ground vomitus in afternoon. Died at 10.40 P. M.

The autopsy was made February 15th, thirty-six hours after death. Rigor mortis present. Lividity of dependent portions. Body well developed, but emaciated. Head and spine not opened. Spleen somewhat enlarged. On the under surface of the right lobe of the liver was an abscess extending about one and a half inches into its substance. The abscess cavity was filled with pus and shreddy masses. It was about the size of a small apple, and its walls were formed by the liver substance and the tissues between the kidney and liver, and was shut off from the general peritoneal cavity by adhesions. There was no peritonitis except in the region of the abscess. Bladder normal, and contained no calculi. Both ureters were somewhat dilated, the right one being blocked by a calculus the size of a thimble, about two inches from the pelvis of the kidney. The walls of both ureters were slightly thickened. Both kidneys were enlarged, lobular and fluctuating. The right was represented by a sac about the size of a new-born baby's head, the sac being filled with a sero-purulent fluid. Of kidney substance there was a piece about a quarter of an inch thick and one inch square in the upper part. There were four or five small calculi in this sac. The left kidney was about the same size as the right, and retained more of the kidney substance. The pelvis was much dilated, and almost entirely filled with a calculus (see cut) weighing fifty grammes and consisting of phosphates. There were numerous small calculi of the same composition, weighing altogether thirty grammes, in the numerous sacs of the kidney. All the other organs presented nothing abnormal.

The surprising thing about this case is the large amount of destruction of the kidney substance, with the short duration of the fatal illness. Of course, the first symptom was the sickness in the spring of 1891, nearly two years before death; but after a short period of illness she was apparently quite well until November, 1892, when the symptoms of her last sickness began. She was not sick enough, according to her story and that of her family, to wish a doctor until just before her entrance to the hospital, January 31st.

---

EXECUTION BY ELECTRICITY. — A bill for execution of death sentences by electricity has been introduced in the West Virginia Legislature.

# Medical Progress.

## RECENT PROGRESS IN OBSTETRICS.

BY EDWARD REYNOLDS, M.D.

### VALVULAR DISEASE AND PREGNANCY.

Vinay [1] has examined the hearts of 1,700 pregnant women, with the object of determining the prognosis of pregnancy in cardiopaths. Among these 1,700 cases he found 29 who were the subjects of cardiac disease, and of these 29 there were only four in whom the pregnancy exerted any deleterious influence upon the cardiac lesion.

He concludes that pregnancy should be forbidden only to those whose heart lesions are not well compensated. He regards albuminuria, dyspnea, hemoptysis, cardiac asthenia, and a social condition which would require the patient to perform hard work during pregnancy as the chief contraindications.

### TUBAL PREGNANCY AND THE TREATMENT OF THE HEMORRHAGES INTO THE ABDOMINAL CAVITY RESULTING FROM THIS CONDITION.

Dührssen [2] suggests the advantage of preceding celiotomies for the acute anemia of ruptured tubal pregnancy by an infusion of normal salt solution. He meets the theoretical objection that this may increase the existing hemorrhage, by operating as soon as the patient's pulse improves, and by a report of successful cases.

### MECHANISM OF THE CLOSING OF THE DUCTUS ARTERIOSUS.

Strassmann [3] reports his exceedingly interesting studies of the mechanism by which the closure of the ductus arteriosus is effected. He has demonstrated from the fifth month in the human fetus a progressive development of the angle made by the anterior wall of the duct at its junction with the aorta, which at term forms a valve which is held open by the current in the duct, but must close before any regurgitant current. He has found similar conditions in fetal sheep, dogs and cats. The closure of the duct is a necessary consequence of the mechanical conditions which follow the first respiration.

During fetal life the full force of the right heart is expended in maintaining the blood current in the ductus arteriosus, and the valve remains open; but with the sudden expansion of the pulmonary arteries by the first respiration, the pressure in the duct becomes much less than that in the aorta; the valve immediately closes, and the closure is maintained by the immediate establishment of the permanent excess of pressure in the circulatory system of the left heart, which is characteristic of extra-uterine life.

The closure is prevented (1) if the first respiration is insufficient; (2) if premature respiration (that is, respiration before the air has access to the mouth) occasions sufficient pressure in the duct to overstretch it; (3) in some abnormal conditions of pressure in the large vessels; (4) in cases of incomplete development.

These conclusions are supported by post-mortem injections both through the aorta and through the duct.

[2] Deutsche med. Woch., 1894, Nos. 2 and 3.
[3] Archiv. für Gyn., Bd. xlv, H. 3.

### HYDRORRHEA GRAVIDARUM.

Chazan [4] discusses the cause of this affection, and concludes that it may arise from several sources. In some cases the fluid may collect between the uterine wall and the membranes as a result of edema of the wall; in other cases it may be due to edema of the membranes; thirdly, he believes that it may be a serous discharge from a persistent allantoic sac; and, finally, he quotes a case in which after a diagnosis of hydrorrhea gravidarum had been made, an examination of the membranes after the birth of a healthy child, showed that the amnion was separated from the chorion, and that there was a hole the size of a quarter-dollar through the membranes at this point. He believes that in this case there was an intermittent drainage of the liquor amnii, and considers this as probably the cause of some cases of hydrorrhea gravidarum.

### THE EFFECT OF VENTRAL FIXATION ON SUBSEQUENT PREGNANCIES.

Löhlein [5] reports two cases of pregnancy in women who had been the subjects of previous ventral fixations. The first patient, a iii-para, had a fixation in July, 1892; menstruation ceased in April, 1893, and severe vomiting appeared in March. This was most troublesome in the third month, and was much worse than in her former pregnancies. In the sixth month bands could be felt extending from the abdominal scar to the wall of the uterus near the fundus. The delivery occurred at term, and during labor the bands were easily apparent, the abdominal scar being drawn up towards the fundus with each contraction of the uterus. In the following March the uterus was found to be in anteflexion, movable, and at a normal height in the pelvis. The author thought that there was a development of the band during pregnancy, and that it involuted with the uterus during the puerperium.

In the second case the uterus had been sutured to the abdominal walls at the end of a myomectomy in November, 1892. Five months later Löhlein was called to see her on account of uncontrollable vomiting, and found her to be three months pregnant. Labor was normal, at term. The fixation band was to be detected during labor, as in the preceding case, and the uterus was subsequently found to be in normal condition.

These cases are certainly interesting, as showing not only that a ventral fixation does not necessarily interfere with the course of a subsequent pregnancy, but also that the growth of the uterus may take place without destroying the band which results from the fixation. The author's conclusion that the severe vomiting in both of these cases may have been due to some other cause will hardly appeal to most minds.

### THE PERMANENT RESULTS OF SYMPHYSEOTOMY.

Von Woerz [6] reports ten symphyseotomies. One died of sepsis; one passed out of observation in good condition; eight were followed for a sufficient length of time to warrant a report of their permanent condition. Seven of them were capable of hard work without inconvenience; but of these one had suffered for some time from incontinence of urine, which was cured

[4] Centralblatt für Gynakologie, 1894, No. 5.
[5] Deutsche med. Woch., 1894, No. 11.
[6] Centralblatt für Gynakologie, 1894, Nos. 36 and 37.

by cold baths. One could not work on her hands and knees without pain in the sacro-iliac joints.

Braum[6] reports eight symphyseotomies, with no death. Six are able to work without inconvenience; one suffers from incontinence of urine and sacro-iliac pain after lifting heavy weights; one has incontinence of urine after straining or lifting.

Among eighteen patients there was then one death, and one patient who passed from observation. Of the sixteen remaining patients, three cannot do heavy work without pain, but are otherwise well, and thirteen suffer no inconvenience.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL OBSERVATION.

J. C. MUMFORD, M.D., SECRETARY.

REGULAR Meeting, Monday, December 3, 1894, DR. S. W. LANGMAID in the chair.

DR. P. C. KNAPP read a paper on

THE TREATMENT OF CHOREA, WITH ESPECIAL REFERENCE TO THE USE OF QUININE.

DR. J. J. PUTNAM: There are several points which are very interesting in Dr. Knapp's paper. I am rather relieved that he takes the view he does with respect to quinine and to arsenic. In regard to the relation of the canine chorea to the ordinary chorea of children, it seems to me to be quite true, as Dr. Knapp has said, that we ought not to reason from one to the other. When we think how many affections there are which resemble chorea, and how long it has taken the neurologist to distinguish between them, it seems very doubtful if we ought to consider that the chorea of the dog is the same with the chorea of Sydenham. The mere fact that it is a spinal disease, whereas the ordinary chorea is almost certainly a cerebral disease, would be enough to make one doubt whether the same remedy would be likely to be useful for both. My own experience with quinine has not been great. I used it a few times, but seeing no benefit gave it up. I have believed very strongly in the arsenical treatment pushed to large doses, though it is true that cases do not get well which one would expect to get well, and it may be true for others that if we let them alone and treated them hygienically they would do well.

As to the origin of chorea, I should like to say that although it may be of microbic origin, the fact is yet to be proved. Dr. Dana's observations cannot be regarded as carrying great weight in that respect, although anatomically they are of much value. Pianese's reasoning was based mainly on observations with dogs, although he did find in the blood of certain choreic patients some organism which he thought to be characteristic, and with which he thought he produced movements comparable with chorea, by injecting them experimentally.

Dr. Knapp says the cases which occur suddenly from fright might be hysterical cases. I do not think I should agree with him there. It seems to me that if it is true that chorea is of microbic origin, it is also possible that it should be induced by fright. We know that the opportunity for microbes to develop seems to be afforded by many agencies that do not have anything to do with the disease except in that way. I think chorea does occur from fright. I recall one case where a boy was startled while climbing a tree, and fell a considerable distance to the ground, and then and there began to have choreic movements, and when I saw him they were typical. It seems to me hardly reasonable to call such cases hysterical.

See page 204 of the Journal.

DR. PRINCE: I regret to say that I personally have had no experience in the treatment of chorea by quinine; but I have no doubt, speaking from general principles, that Dr. Knapp is correct in his conclusions. Reasoning *à priori* I should have very little faith in quinine. But in this connection I should like to say a few words on the treatment of chorea in general. I think all here will agree that there is scarcely any disease in which it is so difficult to determine the effect of treatment as it is in chorea. There are various reasons for this. In the first place, we are obliged very largely to rely upon hospital out-patients for our experiments; and here we are met by difficulties at the outset. In the first place, many hospital patients do not return to report final results. After they see they are better, they are apt not to return, and we do not learn the particular time when the patient has become well. In the second place, it is not always easy to say positively in a hospital out-patient clinic that a patient is well. We are obliged to rely on the statements of the mothers who are, as a rule, not particularly exact. I have always felt so uncertain regarding the exact period when the child was well, that I have sometimes felt discouraged in making up my mind as to the value of any particular treatment. In the third place, chorea varies much like other diseases in its course. Some cases run a very rapid course, get well in a few weeks, and others are prolonged for a very long time; so that it is very difficult, I think, to determine the effect of any treatment we wish to try. Now, there are two ways of testing a treatment. We may judge either by the apparent effect upon an individual case in shortening the disease, or we may have recourse to the statistical method. If we are to judge by the apparent effect upon individual cases as they come, it seems to me to be without doubt that arsenic, for example, does seem to have a beneficial effect. I would say that it is the rule that the parents report the next week after you have given arsenic that the child is better; and if we judge by that kind of evidence it seems to me arsenic must be regarded as beneficial. On the other hand, I am not so certain that that kind of evidence is of value. It is the general tendency of most people, as soon as they find that some one has taken the responsibility off their shoulders, to say that their children are doing well. Now it is frequently impossible in out-patient clinics for a physician in the short time he can give to a case to decide whether or not the choreic movements are increased or lessened. A child may twitch more from the excitement of the clinic or less from mental impression. The tendency of patients to say they are better is true of other diseases. I recall a rather pathetic case in my own experience. It is that of a man with paralysis agitans. Some years ago he came to the clinic for treatment, and I treated him with electricity. I had then more faith in the treatment by electricity of organic diseases of the spinal cord than now. I am afraid I had faith in it then for the same reason that I have faith in arsenic now—because it was the conventional mode of

treatment. I treated this man with electricity; and every week I asked him how he was, and every week he said he was getting better. I was quite satisfied he was not improving, but I had not the heart to tell him he was not better. It went on week after week and month after month, until finally it became necessary to tell him he was no better. He refused to believe me, and insisted that he was better. The next week he came back and shook his head sadly, and said: "Doctor, you are right; I am no better." That same thing is taking place to-day. I have another case of paralysis agitans that insists that she is better. She is not. The same thing is often observed in patients with locomotor ataxia, etc. I think it is a dangerous test, this relying upon the statement of the patient. But if that is true, the only other test we have is the statistical test. In chorea there are difficulties in obtaining statistics, and this difficulty is added to by the great variations in the course of the disease, in individual cases. Some cases get well in a very short time, some in a long time. Now, I want in that connection to refer to a very striking paper, which, although not on chorea, still is instructive as bearing on the conclusions to be drawn from the effect of treatment of any disease. I remember reading sometime ago a paper on the treatment of typhoid fever by the Brand method. The name of the author I do not at this time recall. It was a very able article. The writer, in order to find out what was the normal course of typhoid fever, and what was the natural mortality, tabulated the mortality in successive groups of cases of, I think, about 50 each, as they entered the hospital. The variations in the mortality of successive groups varied greatly, until, if I remember rightly, about 500 cases were recorded. It took about this number to obtain a standard mortality, and eliminate the element of chances. Now this is undoubtedly also true of other diseases. It takes a very large number of cases to eliminate the doctrine of chances, and I am quite certain that in trying to test our treatment of disease by the statistical method until we eliminate the effect of "chance" we cannot tell the effect of any drug. In that connection I will refer here as justifying this scepticism to a series of one hundred cases of chorea treated by sherry wine. These cases were reported in the *British Medical Journal*, in 1881, by Strange. The writer said he was in the habit of treating all his cases with sherry wine, three to six ounces a day; as a result chorea lasted from three to six weeks. Those are pretty good results. If with sherry wine a cure can be effected in three to six weeks, it seems to me that that is as good a treatment as we can have. It may be, of course, that sherry wine has some specific action in chorea, but one may fairly doubt it, as it does not seem plausible. Arsenic may have the same effect. I began sometime ago to try the expectant treatment of chorea, and gave a number of cases compound tincture gentian in a few drop doses. Unfortunately I did not carry the experiment far enough to arrive at results of value. Some of the cases so treated seemed to do about as well as the other cases; but they were too few in number to be of value. I do not wish to deny the action of arsenic. Until some comparative tests are made and the effect of the expectant treatment tried, I shall continue to use arsenic, but be sceptical regarding its specific effects.

Regarding the pathology of chorea I feel absolutely in the dark, and do not feel able to hold any opinion whatsoever; but if I were obliged to make a guess as to what it is, I think I should guess that it is some form of auto-intoxication. I think it is the usual experience that it occurs among ill-nourished children. They are weak, debilitated, anemic and in poor general condition; and I cannot help suspecting that connected with that there is some poisonous principle in the blood which has this peculiar effect on the nervous system. But this is only a guess. It may be a poisoning from a germ-toxine.

It has been my lot to see very few cases of acute chorea in private practice. Such cases as I have seen have been chronic cases. I have not known whether to attribute this to the fact that most cases of chorea are treated by the general practitioner, or whether it has been simply my lot. I should like to ask the general practitioners here whether they see in private practice many cases of chorea, or whether it is a disease which is peculiar to the poor, as some authorities say. I think it is generally regarded as a disease peculiar to hospital practice.

Dr. Harold Williams: I see a good many cases of chorea in my summer practice at Nantucket that are referred to me from different places. There the cases I have are all cases in private practice and most of them in the better classes of life. Dr. Prince speaks of anemia as being a cause of chorea. It has been my view that the chorea was more often the cause of the anemia; that the choreic child with its neurotic constitution and its difficulty in eating and swallowing, is usually poorly nourished because of the disease. I never have had any experience with treating cases with quinine, but Dr. Knapp's paper has been very interesting to me because he takes the same view apparently of chorea that I take. The cases that come to me are almost all of longer duration than Dr. Knapp has spoken of. I should say they are rather more than ten weeks and almost always have been treated by arsenic. It has been my habit to put them on hygienic treatment which I carry out somewhat further than Dr. Knapp does. I put the child to bed if I can, and have a nurse who is gentle to the child, who reads to it and amuses it. I think that is a very important thing, because it is a great question in my mind how great a part worry and fright play in the continuance of chorea; and whether it is the quiet or the change of food or what it may be, the cases almost always do very well. I have not statistics to speak from, but in seeing quite a good many of them, they almost always get well during the summer, and usually with two weeks in bed. It seems to me that rest is the most important part in the treatment of chorea.

Dr. Fay: A year ago last summer, chancing to see, in the Carney Hospital, Dr. J. J. Minot treat a case by giving forty grains of quinine a day, with apparently very rapid recovery, encouraged me to try it on several cases in the out-patient department. I remember one case treated in the latter part of July with rapidly increasing doses, until on August 8th the child was taking twelve grains three times a day with cessation of the acute movements; but the recovery did not become perfect. Cinchonism was discovered after three days of these doses, and after omitting two days the remedy was renewed at ten grains three times a day, and this was sustained for several days. After that only a very light dose could be borne without cinchonism, and the child maintained a very good recovery. In several other cases a larger dose than three or four

grains could not be borne and rest and the usual tonics were resorted to.

DR. PUTNAM: It seems to me it is hardly fair in talking about arsenic to speak of it as if it was supposed to be a specific at all. There are other remedies which affect chorea. A child was given thirty grains of chloral by Gairdner, and slept soundly all night, waking in the morning comparatively well. I suppose very large doses of quinine which produce a profound impression on the nervous system would from time to time do good. I do not see that Dr. Prince does any more than to throw doubt on the other side, and after all, impressions are worth something, though doubts are also useful. I do not think the testimony of statistics is of much value; but one can really form a judgment of more value by examining critically the course of a single case than by statistics of a great many. If you see a patient sick for a long time and give him these powerful remedies, in certain ways, and see the child recover, it is fair to believe that the remedies were of value. The fact that fifty other children got well in a longer or shorter time than that one seems to me to have comparatively little to do with the question under consideration.

There is one class of cases which I think has not been referred to enough and that is the cases which one is in doubt whether to call chorea or not, where children have slight nervous twitching when supposed to be perfectly well, and I think if one could find with them that these slight movements could be inhibited by remedies it would be a very interesting matter. I think they are of importance as regards the theory of chorea, because if there is poison in one case, there ought to be in the other. We can hardly think of a microbic poison acting so long as we see it in these slight movements.

As to rest, I should agree with Dr. Williams and Dr. Knapp. With poor children it is difficult to carry it out. I think to force them to lie in bed is to give them the aggravation and excitement you want to take away. In all cases I have them lie down a half-hour at noon in blankets before dinner, and then have cold sponging.

A single word about the kind of children that have chorea. I have seen it now and then among rich people, although I should say among the delicate ones, but I think it is striking how it occurs in certain races. Negroes are poorly nourished, prone to syphilis and tuberculosis, but do not often have chorea; whereas Hebrews and Portuguese have it with great frequency. We see all these nationalities at the Massachusetts General Hospital and I should rate their liability as follows: Portuguese first, Irish next, Hebrews next, Americans next.

DR. PRINCE: If I may explain myself, I should agree entirely with Dr. Putnam if the conditions were always such as he describes. I can only say that with me they have not been such. If I could go into a private house and watch the movements of chorea from day to day, and should find that in individual cases after giving arsenic that the child began to improve at once, and if I should see that same chain of events happening in a number of children, I should think it fair to assume that arsenic was doing good. But I feel I cannot tell when children come into the room of a hospital clinic, except in extreme cases, whether they are improving or not, until so great improvement has taken place and so long a time has elapsed that it is difficult to say whether it was time or the drugs that have been efficient.

DR. F. L. JACK: I had an idea that the cause of chorea was often reflex. I have in mind a case which I hardly know whether to speak of or not. It was one referred to me, not on account of the twitchings of the arm and face, but because of ear trouble. Upon examining the naso-pharynx a large mass of adenoids was found. I advised and performed an operation. The choreic movements were not considered at all. Two days after, the parents called my attention to the fact that the twitchings were noticeably less. In a week's time they had entirely disappeared, and I know the case ran on nine months without recurrence.

DR. LANGMAID: In regard to Dr. Jack's case, I should think it was not accident at all. It seems to me it was cause and effect, judging from other cases which have been reported. I wanted to ask Dr. Knapp if the fact that chorea in the dog generally followed distemper — as I think it does — is not possibly one reason why quinine has acted so favorably in those cases.

DR. KNAPP: I certainly can say nothing about that point, for my experience with chorea in the dog is too slight. Of course, there is a possibility as I suggested in my paper, that quinine may have some specific action, in case we assume either that the preceding distemper in the dog or the chorea itself be an infectious disease; as we know that quinine is given in other infectious diseases, relieving symptoms, reducing temperature. Of course, we see a certain number of cases of chorea in man that come on in connection with some acute infectious diseases, notably scarlet fever and acute rheumatism, but with regard to association of distemper in the dog with chorea I can say nothing.

My own experience has been, I think, the same as Dr. Prince's about chorea in the poorer classes. Certainly a very small proportion of the cases I see are in private practice, and they are apt to be the very chronic or the very severe acute cases of chorea. I have always had the belief that most of the ordinary mild cases of chorea in the better classes are treated by the family physician. Dr. Williams's suggestion as to rest is certainly a very excellent one. It naturally could not be carried out with hospital patients, and my own experience in private practice is that it is very difficult to keep a child who feels tolerably well in bed, — difficult, indeed, to get it to take more than a couple of hours' rest on a lounge or in bed during the day, even with some one to amuse it. I should like to keep every case of chorea in bed for a week or two at the first of it, but often the children are so restless that I let them get up, as the lesser evil.

DR. S. T. MIXTER read a paper on

## INTESTINAL INCISION AND DRAINAGE IN CASES OF ACUTE PERITONITIS.[1]

DR. J. G. MUMFORD: Any one who sees this manœuvre must be astonished at the extraordinary rapidity with which the patient is relieved by it. It is the same sort of thing as when we give salts or calomel and drain out the bowels, except that in the case of incision the drainage is immediate. The patient, already relieved of the painful distention, comes out of the ether in comfort. To my mind the only objection to the operation is that it takes up a great deal of time. If you open the bowel in three, four, five or more places and sew it up again I should suppose it would

[1] See page 206 of the Journal.

exhaust the patient's strength in very desperate cases. I suppose it is a choice of evils. The fecal fistula almost always heals in the course of a few weeks. It is very uncommon to have one persist.

## Recent Literature.

*First Aid in Illness and Injury.* By James E. Pilcher, M.D., Ph.D., Captain in the Medical Department of the United States Army. Revised edition, with 176 illustrations, 322 pages. New York: Charles Scribner's Sons. 1894.

Dr. Pilcher's idea has been to produce a book which shall be a manual for rapid reference in emergencies, not only for the soldier, but also for the civilian. He has tried to avoid all technicalities or procedures which require medical experience for their efficient employment. The subject is discussed in four parts.

Part I. The construction of the human machine. This is designed to furnish the reader with the knowledge of anatomy and physiology necessary to read intelligently the subsequent chapters.

Part II. The implements of repair. This includes asepsis, antisepsis, knots, bandages, dressings, and similar subjects.

Part III. Accidents and emergencies. This is devoted to a description of the most common emergencies and their appropriate treatment. The emergencies of the battle-field are discussed in two separate chapters.

Part IV. The care of the human machine. This briefly reviews sanitation, hygiene and dietetics.

To facilitate rapid reference the text is so arranged that the important facts are printed in large type. This enables the reader to separate at a glance the essential facts from accessory details or descriptions. The book is extensively illustrated, and has also a complete index. It is of convenient size for transportation. The chapter describing the ambulance-corps drill is an unusual feature, and is accurate. The book is well written, and contains much valuable information. Its author has collected many effective and practical methods of relieving the conditions which usually obtain in surgical emergencies.

*Syllabus of Lectures on Human Embryology.* An Introduction to the Study of Obstetrics and Gynæcology. For medical students and practitioners. With a glossary of embryological terms. By Walter Porter Manton, M.D., Professor of Clinical Gynæcology and Lecturer on Obstetrics in the Detroit College of Medicine; Fellow of the Royal Microscopical Society, of the British Zoölogical Society, American Microscopical Society, etc. Illustrated with 70 outline drawings and Photo-engravings. 12mo, cloth, 126 pages, interleaved for adding notes and other illustrations. Philadelphia: The F. A. Davis Co.

This little work furnishes a brief synopsis of the facts of human embryology. The leading points are emphasized with clearness, so that the book may be conveniently used to refresh one's memory. It is in the main accurate, for we notice few errors; but the notes on the nervous system are far from presenting adequately even the main facts in our present knowledge of that part of the body. This is the only serious criticism against the book, which otherwise is excellent for its purpose.

THE BOSTON

# Medical and Surgical Journal.

THURSDAY, FEBRUARY 28, 1895.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.*

*Remittances should be made by money-order, draft or registered letter, payable to*

## THE AMBULANT TREATMENT OF FRACTURES OF THE LOWER EXTREMITY.

The adoption of the plaster bandage in the treatment of fractures of the lower extremity brought with it a marked shortening of the period of confinement to bed in these injuries. The patient treated by this method, instead of being confined to bed for a month or more, is able, under favorable circumstances, within three or four days to be up and about on crutches, a marked advantage to all patients, and especially to those who bear confinement badly. The results under this treatment, in skilled hands, have been shown to have been fully as good as those of the older methods of treatment, by splints, fracture-boxes, etc., and in many of our larger hospitals the plaster bandage has almost superseded all forms of splint, in the treatment of fractures of the leg, compound as well as simple.

An able and exhaustive editorial in the February number of the *Annals of Surgery* is devoted to the discussion of certain modifications of the plaster bandage, by which patients with broken legs are enabled to walk about, bearing their weight on both limbs, without support of crutch or cane, and without interfering with the union of the broken bones.

In 1891, Krause[1] published a paper on the treatment of fractures of the bones of the leg in walking patients.

Two years later, Korsch[2] published a paper in which he described the application of the ambulant treatment to compound fractures and fractures of the thigh. He applied his plaster bandages directly to the skin, without intervening bandage or padding.

Bruns, of Tübingen,[3] described a method of treating fractures of the thigh by splints made of metal rods and leather straps, the whole leg being suspended, and the weight being brought on the tuber ischii and perineum.

Dollinger, of Budapesth, in 1893,[4] described a re-

[2] Berl. klin. Woch., 1893, No. 2.
[3] Beitrage zur klinische Chirurgie, x Band, 2 Heft, 1893.
[4] Centralblatt für Chirurgie, No. 46, 1893.

movable splint for the ambulant treatment of fractures of the leg.

Bardeleben[5] discussed 116 fractures of the leg patella and thigh, including osteotomies for genu valgum, and compound fractures, treated by the ambulant method.

The advantages of early locomotion, in addition to the great convenience and comfort of the patient, are the prevention of atrophy of the muscles and stiffness of the joints. Delirium tremens is said to be almost unknown in patients treated by this method. The treatment to be successful must be carefully carried out. The bandage should not be applied till the third or fourth day. If any swelling is present when it is applied, it must be removed in a few days, that is, after the subsidence of the swelling, and a new one applied to fit the now altered contour of the limb. In compound fractures, after the first few days have shown that no sepsis is taking place, the ambulant bandage may in the majority of cases be applied.

Korsch demonstrated before the congress at which Bardeleben's paper was read, seven cases, three of the thigh, and four of the leg, in which the ambulant treatment had been practised with good results. In fracture of the thigh passive extension was accomplished by the application of plaster directly to the skin of the malleoli, the dorsum of the foot, and the heel, counter-extension being provided by a Thomas splint of heavy wire, incorporated in the plaster bandage, which extends as high as the tuber ischii. Albers reported at the same congress seventy-eight cases, fifty-six fractures of the leg, five of the patella, sixteen of the thigh, and one of both leg and thigh treated by the ambulant method. Consolidation in malleolar fractures took place in three weeks; in fractures of the middle and lower thirds of the leg in five to six weeks. Fractures of the middle and upper thirds required from three to fourteen weeks. Fractures of the thigh treated early united in from four to five weeks. A compound fracture, converted into a subcutaneous fracture by suture, walked about after the eighth day, and was consolidated on the twenty-seventh. A patient was presented at the congress who ten days before had been run over, sustaining a compound fracture of the left leg and thigh. On the fourth day a "gehverband" was applied, and he walked with the aid of a crutch and cane. In three of Albers's cases of fractured thigh there was no shortening, and in only one case did the shortening amount to three centimetres.

Krause in the discussion at the same congress, claimed to have employed the ambulant treatment for seven years. With regard to the question whether consolidation takes place more rapidly under the ambulant treatment than by the older methods, he presents a table from Paul Bruns which shows in the main that except in fractures of the fibula, which consolidate much more rapidly under the ambulant treatment, there is little difference in the time of union of fractures of the lower third of the leg; but in fractures of the upper third consolidation takes place much earlier. In all these fractures, however, the patients are able to go to work without splints much earlier under the ambulant treatment.

Krause is of the opinion that the ambulant treatment must be limited to fractures and osteotomies in the region of the malleoli, the leg, and the lower end of the femur. He does not employ the method in oblique fractures of the femur or fractures of the neck of the same.

In this country Warbasse has practised the ambulant treatment on six fractures of the leg in the service of Dr. L. S. Pilcher, at the Methodist Episcopal Hospital in Brooklyn. Warbasse does not apply the plaster bandage next the skin, but applies first a flannel bandage from the toes to just above the knee. Twelve or fifteen layers of cotton wadding are included in the flannel bandage beneath the sole of the foot, and the plaster bandage is reinforced by longitudinal turns beneath the sole, and made to fit snugly about the enlargement of the upper end of the tibia. By this method it will be seen that the foot is suspended so that no weight comes on the lower fragment, the weight of the body being borne on the diverging surfaces of the upper end of the tibia, exactly as it is in an artificial leg for an amputation at the point of election. The results in the six cases were as good as those treated in the simple plaster bandage, and some of the patients were able to leave the hospital within three or four days, walking on the injured limb, and returning of course, daily, for observation.

The advantages of the ambulant treatment to the patient, if equally good results can be attained, are obvious enough. On the part of the surgeon it requires much greater care and watchfulness than the older methods. As has been pointed out, the bandage must be changed whenever the subsidence of the swelling has allowed it to become even slightly loosened, for in an ambulant patient the free play of the muscles would be extremely likely both to cause shifting of the ends of the fragments and delayed union or deformity.

As an objection to the general adoption of the treatment in this country, it has been stated that German surgeons were satisfied with results which in this country would bring disrepute upon the surgeon responsible for them. The results attained by Warbasse, however, leave little to be desired. Theoretically, there seems to be no reason why certain uncomplicated fractures of the lower limb cannot be so protected and confined as to allow the patient to walk about during treatment. The treatment, however, can be safely adopted only by those especially skilled in the application of plaster bandage, and should not be attempted under circumstances where the case cannot be constantly and carefully watched. A more extended trial on a large scale, in competent hands, is necessary to establish its value, and the evidence now at hand may be considered to warrant such trial. In the treatment of cases in

[5] Verhandlungen der deutsche Gesellsch. für Chir., 1894.

which confinement to bed is likely to produce delirium tremens the advantages are certainly great enough to justify the attempt.

Korsch's method of applying the plaster bandage next the skin, we think will hardly meet with favor in this country, the danger of pressure sores with their attendant disadvantages being too great. There seems to be no reason why a smooth flannel bandage applied next the skin should interfere with proper immobilization, while it would certainly be necessary to prevent abrasions in walking patients.

## A METROPOLITAN WATER-SUPPLY.

A special report upon a metropolitan water-supply, recently made to the Massachusetts Legislature by the State Board of Health, will attract much attention. It promises to provide a water of much better quality than Boston has thus far succeeded in getting, to a population of nearly two million people. It is possible to furnish this better water, because the country from which the supply is to come is the sparsely settled territory on the southern and eastern slopes of Wachusett mountain, with a poor soil, and possessing no temptations to a manufacturing population; moreover, it is comparatively free from swamps, the presence of which gives so decided a color to the waters of the Sudbury, Boston's present chief source of supply.

The plan now presented has the additional merit, that still other sources of very pure water, sufficient for any period of time for which provision should be made, can be conveniently and cheaply united to this new supply.

The important hearing before a committee of the City Council of Boston some ten years since, is probably still remembered by careful readers of the Journal. Upon that occasion many of our prominent physicians and other citizens insisted upon the more thorough removal of the soil from basins intended for the storage of water used for domestic supply.

It will also be remembered, how great the improvement was, that followed the application of this treatment to two of the basins of the Sudbury system, which had at first not been so treated; acting upon the instruction of that lesson, the authorities of Boston have caused the more recent basins, constructed on the same water-shed, to receive a more elaborate preparation even.

Such experiences as these of the City of Boston, in connection with the results obtained at the experiment station of the State Board of Health at Lawrence, prove that the great basins of a water-supply cannot be too carefully prepared for their work. So decidedly of this opinion does the board appear to be, that they state that nearly $4,000,000 of the $19,000,000 estimated to be the total cost of the new supply are to be spent upon measures of preparation immediately designed for the purpose of getting a colorless and attractive water, equal to that found in Lake Winnipiseogee.

For more than a generation men have looked to this New Hampshire lake as the ideal water-supply for the greater Boston. This report seems to have, at last, restored this charming pleasure resort to the unhampered enjoyment of the people of the whole country. It is altogether probable that the State of New Hampshire would not surrender its control of the lake, to begin with; and it now appears that the water is to a certain degree polluted and likely in the future to become much more so, and therefore undesirable.

At first sight it is a surprise to find the board turning away so decidedly from the scheme to bring down to the metropolitan district the filtered waters of the Merrimack. It was understood that they have been satisfied with the results of the use of the filtered water at Lawrence, and some threatened legal complications might have been avoided by taking water at a point where citizens only of this State were to be affected. But we must confess that the conclusion arrived at to pay a little more and take a water above suspicion, is sound and will, we believe, meet with general approval. It has been both wittily and wisely said that what we demand of a drinking-water is not repentance but purity. There is another objection to be urged against a great filter plant employing a hundred or more attendants, which is not mentioned, although the board may have had it in mind, and it is this — the possibility of a strike among the workmen, and the consequent disturbance in the supply of the most important need of our lives.

From beginning to end the report is full of interest, and should be read by every physician within the proposed district.

## NERVOUS DISEASES AND MODERN LIFE.

Dr. Clifford Allbutt, in the *Contemporary Review* for February, 1895, discusses the subject of "Nervous Diseases and Modern Life."

His lengthy article, whose prolixity is only relieved by its rhetorical brilliancy, is written from an optimistic standpoint, and opposes the prevalent view that nervous diseases are on the increase.

We may admit the arduousness of the struggle for existence without conceding that the civilized races are degenerating, and that in the evolution of our race the complex brain is becoming more and more unstable, and more prone to be upset by faulty surroundings and high-pressure life. In spite of the more direct and brutal elimination of the unfit among savages, we see obscurely in the gloom of the past or of the remoter parts of the earth that possession by devils, attacks of fury, hallucinations, frenzies and epidemic manias have been at least as common in savage peoples as in our own. On this point Dr. Tyler ("Primitive Culture") gives some striking facts.

Again, there are many diseases classed as nervous diseases which may not strictly belong to this class, or only belong to it in an anatomical sense. When disease of the skull invades the brain, the resulting

disorders are not to be regarded as primarily nervous; so, again, if the brain suffer from disease of the blood-vessels, we ought not to regard the consequent disorders as nervous in their nature. Again, certain specific affections of the nervous tissues may be secondary to intoxications, such as lead, alcohol, diphtheria, influenza, and so on; and in such cases we must acquit the nervous system of primary defect.

Dr. Allbutt believes that the widest observation will show that by virtue of its more and more complete adaptation to the varying degrees and kinds of social pressure — that is to say, of its very complexity — the nervous tissue, delicate as it is, exquisite as it is, shows a tenacity and persistence beyond most others. Old age rarely enters by the paths of the nerves or finds its first seat in the cerebral centres. If the circulation be maintained, and the excretions do not fail, the brain of old persons retains a marvellous efficiency.

Dr. Allbutt's paper brings out forcibly the relation of work to the nervous system. It is not systematic work that does harm so much as prevalent vices and sins against obvious hygiene. Distress, anxiety and worry are factors rather of alimentary and cardio-renal than of nervous disease. Many a nervous breakdown begins in a derangement of digestion; and in most instances of neuropathy ascribed to overwork, it is rather the conditions under which work is done than the work itself which has done the mischief. Many a woman works away mechanically, regardless of the hours of rest, taking little or taking improper food, poisoning her nerves with tea and her blood with impure air, and then becomes nervous and hysterical. On the other hand, the men or women who, having inherited a fairly stable nervous system, work their brains so as to get most out of them, who are temperate in meat and drink, and take care to breathe fresh air, will have little complaint to make of nervousness.

"Morbid heredity and vice apart," says the writer, "the nervous system bears ill usage as well as any other part of our bodies."

General paralysis is, no doubt, a disease of towns, and more and more, therefore, of modern life. That it has, however, no close dependence on brain work or the hurry and worry of business, is evident from its frequency among soldiers and sailors, who, although they frequent towns, belong rather to the country or the sea. The characters of this disease are such as, in the estimation of Dr. Allbutt, might warrant its classification apart from the primarily nervous, and perhaps among the infectious diseases.

It might be supposed that insanity is on the increase in certain arduous business pursuits, where the nervous wear and tear is exceptionally severe; but here, too, according to this writer, there are no official returns to justify any such inference. On the contrary, we find it just as prevalent in other callings in which nervous and mental strain is not an important factor. Classification of the insane by calling has thrown as yet but little light on causation, except in so far as the negative results fortify the belief that insanity is rather a result of physical degeneration and of hereditary transmission than of overwork and anxiety. "The increase of insanity is greatest," says Dr. Ogle, "in the agricultural laborer who does not speculate in stocks, and who lives in Arcadian peace and simplicity."

Grim as are the stories of individual trials and sorrows which are told to the physician, madness is a rare consequence of these trials, if we set aside the cases of persons predisposed to the disease. On the other hand, Dr. Allbutt says, "insanity is common enough in quiet old maids, in careless lads and lasses, in humdrum and respectable citizens of all sorts, in rustic squires, in the country clergy, in retired students, in mothers of peaceful homes, and so forth. And of most of these, whatever their lives may have been, we shall find a record of previous insanity in the family tree."

As far as statistics give any light on the subject, it has been shown that the number of insane persons officially recorded is lower by ten per cent. than the number returned as insane at the last census. This is in spite of the fact that demented and insane persons, formerly kept at home or in work-houses, are being more and more massed in asylums, and thus brought under official cognizance.

The Asylums Committee of the Dorsetshire County Council in the last report announce an ebb in the tide of insanity, and to the same purport, according to Dr. Allbutt, is the Registrar-General's Report in the census of 1891.

Finally, Dr. Allbutt insists in glowing terms that there is not degeneration but marked improvement in the physique and nervous stamina of the race; the young men and young women of to-day are stronger and more robust than their predecessors. This he attributes principally to the better sanitation of the present day, and the more scientific regulation of all the habits of life. In the case of women, it is "the enfranchisement of their faculties in a liberal education," and their greater freedom to choose their callings. The general answer, he says, to those who prate of our over-educated and over-pressed boys and girls is "Fudge." "We do our best to hurt them by our clumsy and indiscriminate methods, and we do some harm here and there; but happily there is a fund of elasticity and *insouciance* in healthy youth which, blunder as we may, we cannot crush. I have met with a few cases of naturally healthy undergraduates exhausted by intense study extending over some years; but such cases are rare, and in even these I suspect that want of exercise, fresh air and change of scene were more to be blamed than study itself."

We have heard of such cases in England, and they are from time to time reported in this country; generally the whole story is not told. Neither study nor athletics, as a rule, kill or disable young people, but ignorance and foolishness.

## MEDICAL NOTES.

CHOLERA IN CONSTANTINOPLE. — In the week following February 8th there were sixty-one cases of cholera in Constantinople, and twenty-nine deaths.

THE CONGRESS OF GERMAN SURGEONS. — The Twenty-fourth Congress of German Surgeons will be held at Berlin from the 17th to the 20th of April next. Professor Gussenbauer will preside.

A MONUMENT TO BILLROTH. — A monument to the memory of Professor Billroth will soon be erected in the court of honor of the University of Vienna. The Council of the Faculty has also decided to erect a monument to Skoda and Rokitansky.

JOURNALISM IN JAPAN. — Japan, says a writer in *La Médecine Moderne*, has now over 400 daily journals and 300 reviews. The pioneer in journalism in Japan is said to have been the proprietor of a patent medicine who started a journal to advertise his drugs.

THE TREATMENT OF TUBERCULOUS MENINGITIS. — Dr. R. Hirschberg reports a single case which was successfully treated by trephining and drainage of the sub-arachnoid space. The effect of the operation was remarkable, the headache ceased, the pulse became more rapid, the commencing coma disappeared, as well as the vomiting.— *Bulletin Général de Thérapeutique.*

UNUSUAL POSITION OF A PRIMARY LESION. — Dr. Voll, of Wurzburg, reports in the *Münchener med. Wochenschrift* for January 29th, a case of syphilis in a twenty-two-year-old woman, in which the primary lesion was situated on the back over the tenth rib about eight to ten centimetres from the middle line. The manner in which infection occurred in so curious a position, he leaves to conjecture.

A SERIOUS ATTACK OF HOMESICKNESS. — It is said to be extremely difficult for natives of Brittany to become acclimated outside their native province. An illustration of this fact was given recently in the 162d regiment of French Infantry in garrison at Commercy. This regiment received an addition of eight hundred young soldiers from Finisterre and Morbihan and within eight weeks two of them had hung themselves on account of homesickness. — *Le Progrès Médical.*

A NOVEL REASON FOR NOT INJECTING SUBJECTS FOR DISSECTION. — According to *La Médecine Moderne*, the sanitary authorities of Kieff have complained of the cadaveric odors which emanate from the dissecting rooms of the medical school in that city, and are a nuisance in the neighborhood. It seems that the medical faculty do not allow the subjects for dissection to be preserved by antiseptic injections, for the reason that this would prevent the students from acquiring practical experience in medico-legal autopsies!

ANTITOXIN OF DIPHTHERIA IN CLEVELAND. — Dr A. P. Ohlmacher, director of the pathological and bacteriological laboratories of the medical department of the University of Wooster, Cleveland, O., claims to have rendered a horse immune against diphtheria in one month and sixteen days, a remarkably short period. He also claims that this horse is the first one rendered immune to diphtheria in this country. As soon as he has standardized the serum, he proposes to begin to use it on patients, we hope with successful results.

A HOSPITAL INTERNE TREATED WITH ANTITOXIN. — M. Chabry, an interne at the Hôpital Trousseau, recently contracted a severe type of diphtheria while he was on duty in the diphtheria wards. As soon as the membrane appeared in the pharynx and the Löffler bacilli were found, he was given thirty cubic centimetres of the antitoxin from the Institut Pasteur. His condition, which was grave on the day of the injection, improved markedly on the day following. The serum injections were repeated, and he was soon out of danger. It is certainly sad to think of the number of hospital internes dead of diphtheria whose lives might have been saved by antitoxin.

A NEW NAME FOR THE CARTILAGE OF WRISBERG. — Prof. B. Fraenkel, of Berlin, has lately established the fact that the little cartilage in the ary-epiglottic fold, known as the cartilage of Wrisberg, was first described by Morgagni in the *Adversaria Anatomica.* It was rediscovered in 1770 by the German anatomist Perer Camper. Fraenkel therefore proposes that the proper name be dropped and that the cartilage be designated simply by the term cuneiform, as suggested by Cuvier.— *La Médecine Moderne.*

PHOTOGRAPHING THE UTERUS. — The *American Practitioner and News* is authority for the statement that a Swiss physician has described a method of dilating the uterus by means of tents, so that by the use of a mirror a perfect view may be obtained of the interior of the organ. Not content with this, however, he is enthusiastic enough to desire to obtain photographs of the uterine interior in various diseases of the organ. The future of woman is sad indeed if now her womb must not be only felt of, sounded, and measured, but photographed as well.

THE GERMAN MEDICAL CONGRESS. — The value of antitoxin serum in the treatment of diphtheria is one of the principal subjects set down for discussion at the German Medical Congress to be held at Munich from April 2d to 5th. The subject will be introduced by Professor Heubner of Berlin, and Prof. A. Baginsky of Berlin will read a paper on the subsidiary effects of the serum. The other subjects selected for special discussion are the therapeutics of iron, to be introduced by Professors Quincke, of Kiel, and Bunge, of Basel; and the pathology and treatment of typhlitis, to be introduced by Professors Sahli, of Bern, and Helferich, of Greifswald. An exhibition of apparatus, instruments, and preparations will be held during the Congress.

SYMPHYSEOTOMY IN ENGLAND. — At the annual meeting of the Obstetrical Society recently, Dr. Walter Griffith showed a patient upon whom he had performed symphyseotomy on October 19, 1894, at Queen Charlotte's Hospital. She was thirty-two years of age,

and a primipara. There was pelvic contraction, the true conjugate being three and one-quarter inches. The patient made an excellent recovery, and when exhibited was able to jump down from a chair. She was in very good health, and perfectly able to attend to her work. Dr. Griffith commended Tarnier's practice, in so far as the distinguished French obstetrician's method of performing symphyseotomy was concerned, but did not agree with the theory that the forceps and induction of premature labor ought to be discarded. — *British Medical Journal.*

AN EPIDEMIC PREDICTED. — Colonel Maurice calls attention, in the *United Service Magazine*, to the Chinese claim that there are 500,000 men massed around Pekin. This force has already been there for some time, and it is likely to remain for several months longer. It is an elementary maxim of military tactics that a large force of men should not be gathered until a short time before they are to be employed; otherwise an epidemic, resulting from enforced lack of sanitary arrangements, is almost inevitable. Therefore, the writer predicts that as soon as warm weather begins in the spring there will be a most frightful outbreak of pestilence in some form or other, probably in many forms, but beginning with malignant typhus in its most virulent shape. Colonel Maurice suggests that while there is yet time all foreigners in Pekin be withdrawn under adequate protection.

"ONE MAN ONE JOB." — The February number of the *Practitioner* gives the following story told by Sir George Johnson, president of the Royal College of Physicians, at a dinner of the Laryngological Society, in illustration of the extraordinary firmness with which this one-man-one-job principle is rooted in the public mind. "He (Sir George Johnson) was once sent for to see a lady who had consulted him several times for some affection of the throat. He found that she was suffering from Bright's disease. When the husband was informed of his wife's condition, he at once sent for another physician, taking it for granted that Sir George Johnson's knowledge did not extend to the kidneys. The poor lady died in a few days of her renal complaint, having very possibly fallen a victim to the absurd delusion that each man must have his own little 'allotment' in the human body, and must not trespass on any other."

A CASE OF MALPRACTICE. — Dr. Farnsworth, of Clinton, Ia., reports the following case in the *Medical and Surgical Reporter:* "The Spitz dog of a highly respectable family of this city had a difficulty with his throat. Respiration impeded; deglutition difficult. The carriage was ordered out and 'Tip' was taken to a leading surgeon. The latter diagnosed stenosis or tumor of the larynx in the neighborhood of the vocal cords, as Tip's bark had sailed away and was lost at C. An examination confirmed this diagnosis, and under chloroform an operation was performed. The dog died. At post-mortem examination it was found that some one had slipped over his head a rubber band such as druggists use to tie up packages. It had worked through the hair and bedded itself in the skin. In any case it was the cause of the dog's death, and the bereaved are now querying where to fix the blame."

### BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, February 27, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 59, scarlet fever 30, measles 23, typhoid fever 2.

A STEP TOWARDS EXTRA-MURAL TEACHING. — The Medical Faculty of Harvard University has voted to authorize approved physicians having the necessary facilities and desirous of teaching its medical students, to announce their courses yearly in the Medical School. Such announcements should be sent to the Committee on Applications to Teach, which consists of E. H. Bradford (Chairman), R. H. Fitz, W. T. Porter.

FOUR YEARS' COURSE AT THE YALE MEDICAL SCHOOL. — The faculty of the medical department of Yale University has decided to extend the course from three to four years, and a committee has been appointed to perfect plans for the new course.

## Miscellany.

### HEROIC TREATMENT.

IN an article in the *Edinburgh Medical Journal*, on "An Episode in Medical History," Dr. G. W. Balfour gives an account of the extent to which the treatment by blood-letting was carried when at the height of its popularity. The case of Betsey Moffat, reported in the *Edinburgh Medical Journal* for September, 1865, is well worthy of record. Dr. Balfour's account is as follows: "Admitted to hospital with a sharp attack of pneumonia, she was freely bled from the arm, besides undergoing other lowering (so-called antiphlogistic) treatment; in a fortnight she was dismissed as cured. Ten days subsequently she was re-admitted with a recurrence of all her symptoms, and a pulse of 130; she was treated as formerly by repeated venesections, etc. After two days she lay insensible, with a feeble pulse of 104, and a rattle in her throat like one dying; even her physician, Professor Gregory, admitted that she could not be further bled; but after he had stimulated her with hartshorn and sack-whey, he was able before leaving the ward to apply a few leeches to her head, and he was subsequently able to take four ounces of blood from her arm. It is satisfactory to find it recorded that Betsey Moffat recovered. One scarce knows whether to admire most the boldness of the physician or the luck of the patient."

Dr. Balfour ascribes the popularity of blood-letting at that time to the confidence established by the physician, who when in doubt, has recourse to bold measures, and if successful, acquires the reputation for daring and courage in life-saving treatment. If death occurs after such treatment, the statement can certainly be made that the most radical treatment has failed to give relief, in spite of prompt and thorough resort to it.

Dr. Balfour gives the following anecdote to establish the principle that among rude and savage peoples any treatment that shows power is regarded with respect, and does no harm to the practitioner, whatever becomes of the patient:

"'What devil is in this salt?' said an Afghan physician to the traveller Ferrier, showing him some cyanide of mercury; 'for of a hundred patients to whom I have given it only one has survived.' This active practice did the physician no harm among his barbarous compeers, with whom weakness is the only unpardonable sin."

That in our day this position of things is reversed is shown by the success of quacks who advertise the treatment of cancer, etc., by palliative measures, and gain a large practice at the expense of regular practitioners who have advised operation as the only method of treatment which can give hope of success. In many ways we seem to have degenerated since the days when heroic treatment ensured a physician's popularity. The "rude and savage peoples" who respect any treatment which shows power, would often stand a better chance of getting well, than many of the more highly civilized members of modern society.

## Correspondence.

### A DEFINITION OF INFLUENZA.

LAWRENCE, MASS., February 22, 1895.

MR. EDITOR: — A clerical acquaintance defines influenza (grippe) as "a 'cold' possessed of the Devil."

Very truly yours,

C. G. CARLETON, M.D.

### QUESTIONS ABOUT DIPHTHERIA ANTITOXIN.

NASHUA, N. H., February 18, 1895.

MR. EDITOR: — For my own benefit — and I think it would interest the medical profession — I would be thankful to you if you would kindly answer the few following questions about diphtheria antitoxin in the JOURNAL.

(1) I have seen that in London an eminent physician reported to a medical society that Behring's antitoxin caused albuminuria and casts were found in the urine. Have those effects been noticed here, with Behring's or any other antitoxin?

(2) I have seen notices that antitoxin (German) would gain strength for a few days or weeks, but after some time it would lose its properties. Is this true?

(3) If this (in No. 2) is true, antitoxin must therefore be fresh to have its full curative and preventative effects?

(4) Would you kindly inform me how long antitoxin will keep?

(5) Has the antitoxin of the Pasteur Institute, N. Y. (Roux formula) been used extensively in the hospitals in Boston?

(6) Where can I get, in case of emergency, the antitoxin that is fresh?

(7) How long does it take for the foreign antitoxin to get to the consumer here after it is made?

Yours very truly,

C. B. HAMMOND, M.D., *City Physician.*

[Nephritis is a sequel of diphtheria in some cases where antitoxin has not been used. It has also been reported in some cases where antitoxin has been used. The possibility of its occurrence does not contraindicate the use of antitoxin. The German diphtheria antitoxin is supposed to retain its qualities about five months. Whether one maker's antitoxin will be fresher or will keep longer than another's we cannot undertake to say, any more than we say what the age of any given specimen may be. Each dealer must guarantee the age and quality of his own article. — ED.]

### GALACTOPATHY.

BOSTON, February 22, 1895.

MR. EDITOR: — Dr. W. B. Sampson writes from the Transvaal, South Africa, to call attention to the advantages, in zymotic diseases, of a wet pack; not, however, of water, but of warm milk. An epidemic of typhoid fever, due to the use of milk which had stood in buckets previously washed in water subsequently ascertained to be infected, suggested the idea that, if milk would so easily absorb germs from wood, it might do the same from the human body. Experiments in cases of erysipelas seemed to confirm the truth of this theory, and, accordingly, in an epidemic of small-pox, galactopathy was substituted for hydropathy to reduce fever, prevent pitting, and soothe the nervous system; perhaps, also, in some degree, to nourish the patient. Three blankets were laid upon a mattress, and covered by a single sheet saturated with one and a half pints of fresh, warm milk (not boiled). The patient was laid upon the sheet. This was then wound tightly around him, the ends brought over his shoulders, and his arms left bare. The blankets were then, one by one, packed over him, and he rested thus for an hour. This was done once in four hours. After the pack, a warm bath or sponging.

Dr. Sampson reports that in eighteen cases so treated by him, in the small-pox lazaretto at Kimberley, before the eruption appeared, the disease was *aborted*, and the patient convalescent in five days. In one case, where the eruption had just manifested itself, the milk-pack was used twice as often. The eruption disappeared entirely within twenty-four hours, and in four days the patient was able to leave his bed.

Subsequent experiments in cases of the various infective fevers gave good results. The milk-pack was found to lower temperature, stop delirium, procure comfort for the patient and promote sleep. It is, in its action, gentle, soothing and wonderfully recuperative. It causes no weakening, but increases the patient's flesh and strength. Tried side by side with hydropathic wet-sheet packing, the superiority of the milk-pack was manifest.

In scarlet-fever, measles, typhus, typhoid, and even malarial and puerperal fevers, remarkable results were obtained. One case of scarlet fever yielded in three days. Milk compresses to the throat in diphtheria gave the best results. If this remedy should really prove as efficacious as it is simple, therapeutics has made an advance.

Very truly yours,

E. WIGGLESWORTH, M.D.

### METEOROLOGICAL RECORD,

For the week ending February 16th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer | Thermometer. | | | Relative humidity. | | | Direction of wind. | | Velocity of wind. | | Weather. | | Rainfall in inches. |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|

| Gloucester | 27,293 | — | — | — | — | — | — | — |
| Taunton | 26,964 | 12 | 1 | 8.33 | 8.33 | — | 8.33 | — |
| Waltham | 22,058 | 6 | 1 | — | 33.33 | — | — | — |
| Quincy | 19,642 | 1 | 0 | — | — | — | — | — |
| Pittsfield | 18,862 | 5 | 0 | — | 20.00 | — | — | — |
| Everett | 16,585 | 11 | 5 | 9.09 | — | — | — | 9.09 |
| Northampton | 16,331 | 5 | 3 | — | 60.00 | — | — | — |
| Newburyport | 14,073 | 4 | 0 | — | — | — | — | — |
| Amesbury | 10,920 | 7 | 1 | 14.28 | 28.56 | — | — | — |

Deaths reported 3,269: under five years of age 1,098; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 296, acute lung diseases 723, consumption 372, diphtheria and croup 128, scarlet fever 43, typhoid fever 41, diarrheal diseases 39, whooping-cough 15, measles and erysipelas 11 each, cerebro-spinal meningitis 7, small-pox 1.

From diarrheal diseases New York 12, Philadelphia 8, Boston and Cincinnati 4 each, Fall River 3, Brooklyn, Washington and Lowell 2 each, Cleveland and Salem 1 each. From whooping-cough New York 5, Brooklyn 4, Philadelphia and Cincinnati 2 each, Washington and Worcester 1 each. From measles New York 4, Brooklyn 3, Providence 2, Boston and Somerville 1 each. From erysipelas Brooklyn 4, New York 3, Philadelphia 2, Providence 1. From cerebro-spinal meningitis New York 2, Philadelphia, Washington, Cleveland, Fall River and Marlborough 1 each. From small-pox Philadelphia 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530, for the week ending February 9th, the death-rate was 20.7. Deaths reported 4,210: acute diseases of the respiratory organs (London) 480, whooping-cough 78, diphtheria 67, measles 56, diarrhea 39, fever 36, scarlet fever 32, small-pox (London 3, Derby 1) 4.

The death-rates ranged from 13.5 in Derby to 30.9 in Liverpool; Birmingham 22.3, Bradford 15.0, Cardiff 22.4, Croydon 18.1, Hull 20.2, Leeds 17.5, Leicester 14.5, London 21.0, Manchester 24.8, Newcastle-on-Tyne 19.4, Nottingham 18.2, Portsmouth 19.7, Sheffield 17.6, Swansea 21.0, Wolverhampton 23.7.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 16, 1895, TO FEBRUARY 21, 1895.

CAPTAIN HENRY P. BIRMINGHAM, assistant surgeon, is relieved from duty at Fort Grant, Arizona Territory, and ordered to Fort Trumbull, Conn., for duty, relieving CAPTAIN FREEMAN V. WALKER, assistant surgeon.

CAPTAIN WALKER, on being thus relieved, will proceed to Fort Grant, Arizona, and report for duty at that post.

The extension of leave of absence granted FIRST-LIEUT. HENRY C. FISHER, assistant surgeon, is further extended one month.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 23, 1895.

CLEMENT BIDDLE, passed assistant surgeon, ordered to Naval Hospital, Chelsea, Mass.

L. W. ATLEE, passed assistant surgeon, ordered to Naval Hospital, New York, N. Y.

F. A. HESLER, passed assistant surgeon, ordered before Retiring Board.

## SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.— A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday evening, March 4th, at 8 o'clock.

Dr. J. J. Putnam will read a paper entitled: "Psychical Treatment of Neurasthenia."

Dr. H. L. Smith on "Cases Illustrating the Plastic Surgery of the Nose and Palate: Description of an Operation for Cleft Palate." Discussion by Drs. H. A. Baker and Geo. F. Grant, who will be present by invitation.

JAMES G. MUMFORD, M.D., *Secretary*.

THE WARREN CLUB.— A regular meeting of the Club will be held at 11 Marlborough Street, on Tuesday evening, March 5th, at 8 o'clock.

Dr. Malcolm Storer: "A Consideration of Axial Rotation with Especial Reference to the Torsion of Ovarian Tumors."

Dr. F. C. Cobb: "The Cavities Accessory to the Nasal Cavities."

Dr. C. L. Scudder: "Case of Middle Meningeal Hemorrhage from Contre-Coup; Trephining; Recovery."

W. E. PAUL, M.D., *Secretary*.

THE SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION.— The Surgical Section of the Suffolk District Medical Society will hold its regular monthly meeting at 19 Boylston Place, on Wednesday evening, March 6th, at 8 o'clock.

Dr. Roswell Park, of Buffalo, will present a paper upon "Acute Infectious Processes in Bone."

It is hoped that a large number may enjoy the privilege of listening to the discussion of a subject of so great importance. An opportunity for the presentation of pathological specimens will be given after the discussion of the paper.

C. L. SCUDDER, M.D., *Secretary*.

NORFOLK DISTRICT MEDICAL SOCIETY.— The Brookline Fellows of the Norfolk District Medical Society cordially invite the Society to a meeting for Scientific Improvement, to be held at the Town Hall, Brookline, on Tuesday, February 26, 1895, at 7.45 P. M.

"Massage in Sprains, Bruises and Dislocations," Douglas Graham, M.D.

"Treatment of Congenital Club-Foot," P. C. Proctor, M.D. Discussion to be opened by E. G. Brackett.

"A Suggestion Concerning the Preservation of the American Physique," J. W. Achorn, M.D.

Lunch at 9.45 P. M.

J. C. D. PIGEON, M.D., *Secretary*.

AMERICAN MEDICAL ASSOCIATION.— The Section on Neurology and Medical Jurisprudence have arranged the following symposiums for the annual meeting at Baltimore, Md., May 7, 1895.

"Epilepsy: Medically, Surgically and Therapeutically." "Hypnotism and Mental Therapeutics, and its Medico-Legal Relations." "Electricity: Some New Therapeutical Relations and Questions of Treatment."

Short practical papers on these topics are urgently solicited. Other papers on subjects belonging to this Section will be welcomed. Address

T. D. CROTHERS, M.D., *Secretary*, Hartford, Conn.

## BOOKS AND PAMPHLETS RECEIVED.

Hospitals for the Insane; Their Scope and Design. By Edward F. Wells, M.D., Chicago. Reprint. 1895.

Experiments and Observations on the Summer Ventilation and Cooling of Hospitals. By Morrill Wyman. Reprint. 1895.

### THE SURGICAL TREATMENT OF FIBROID TUMORS OF THE UTERUS.[1]

BY JOHN HOMANS, M.D.,
*Surgeon to the Massachusetts General Hospital, etc.*

IN what I have to say in regard to the treatment of fibroids, I shall not attempt to mention all the names of the very eminent operators who have written on the subject. I doubt if one man could read in a day the communications published during twenty-four hours on this subject. You can read them for yourselves in the *American Journal of Obstetrics* and in the various other journals and medical magazines published at home and abroad. My remarks will be drawn from my own experience, and, such as I have to make, would be confused and uninteresting if mixed up with references to others' writings, so I will not try to mention all those I would like to, because I think it would lessen your interest in the subject and make my paper too long. Let me say at the beginning that my remarks will have no reference to fibroids presenting themselves at the uterine or vaginal outlets. For such the proper treatment is removal per vaginam, and this has always been successfully done by me in all cases where the patient had not become septic; this last condition being common where a large fibroid of many pounds' weight has begun to protrude after labor, the condition not being recognized by the attending physician for some days, until sloughing fibroid, uterus, and the patient herself have become thoroughly septic. So much for fibroids extruding or being expelled from the uterus. What I have to say will be limited to the surgical treatment of fibroids after the abdominal cavity has been opened. The dealing with fibroids by abdominal ablation is becoming more common as we become more certainly successful in our methods of operating, and feel confident that we can remove a non-adherent fibroid tumor in a fairly healthy woman without much violence and with almost sure promise of success.

Fibroids do not always cease to grow at the menopause; many of them do, but in many cases they grow and give rise to hemorrhage and other serious symptoms. They also sometimes become cancerous. This condition I have seen twice. Wisdom is shown in choosing the cases requiring operation.

The reasons which lead me to remove a fibroid by abdominal section are: (1) If it actually causes much discomfort. (2) If it threatens death by hemorrhage (and it does sometimes not only threaten, but causes it as suddenly as a pulmonary hemorrhage does). (3) Because it may increase and become too burdensome to allow life to be worth living. (4) Because it may develop a cancerous character. (5) Because by its pressure on the abdominal organs it may destroy life. (6) Because it may become cystic and thoroughly adherent. Such a tumor I have never successfully removed. I do not mean fibroids with dilated lymph-spaces, but fibroids with cysts as clear and distinct as those in ovarian tumors. (7) Because it may be an ever-present anxiety. (8) Because it may cause edema of one or of both extremities and phlebitis, to be followed perhaps by the passage of an embolus into the circulation, causing death by renal or hepatic disease. (9) Because they sometimes are twisted with the uterus as a pedicle and must be removed at once to save life. I have seen this once. (10) Because a very sensitive single woman, in good health, and active, demands its removal on account of the disfigurement it causes. (11) Because the operation, to-day, in experienced hands, is almost uniformly successful. The mortality from all cases, promising and unpromising, probably varies between three and ten per cent. The reasons for not operating are: (1) When the tumor gives no trouble, uneasiness or disturbance and the patient does not desire its removal. (2) When it is not accompanied by hemorrhages. (3) Because no one can positively say that it may not remain stationary or even retrograde. Without being omniscient, we cannot tell the future course of a fibroid. I have watched some tumors twenty years and more, and then removed them because they have grown and become annoying, and I have watched others grow smaller; but I operate more frequently than I used to. I have seen about 650 fibroids, and I have operated on but 93. I should have done well to have operated upon a greater proportion of them.

Some years ago, in 1887, I think, my friend Dr. Keith, then of Edinburgh, now of London, wrote me that I must lay down my knife from fibroids and that they could be treated successfully, that is, made bearable, by electrolysis, *à la* Apostoli. To this treatment I gave a thorough trial for nearly three years, and then abandoned it as a routine method, as uncertain, unsatisfactory and tiresome in the extreme; but I still use it in certain cases of hemorrhage and pain in a patient otherwise strong and whose tumor is quiescent. I published all my electrolysis cases, results, and conclusions in the Boston *Medical and Surgical Journal* for March 12, 1891. The cure of fibroids by removal of the ovaries and tubes is uncertain. Perhaps the ligature of the ovarian artery by cutting off a portion of the blood-supply to the uterus has much to do with the success which sometimes attends this procedure. I have seen a fibroid the size of a cricket-ball entirely disappear at the end of four weeks after removal of the ovaries and tubes, and I have seen some continue to grow, and one to be extruded from the os uteri two years after removal of the ovaries and tubes, the tumor having become a large polypoid growth, and the woman had lost her ovaries unnecessarily two years before. I think we may dismiss this plan of treating fibroids by removal of the ovaries and tubes as uncertain and unreliable. As I have said before, it does not seem necessary to enumerate all the surgeons who have contributed to the literature of the treatment of fibroid tumors. In the United States Martin, Dudley, Gordon, Baer, Baldy, Byford, Kelley, Edebohls, Polk, Price, Krug and others have reported excellent work and intelligent practical measures. In Germany, besides Schroeder, Hager, Kaltenbach and many others have written on this subject. The method which I have gradually, and independently, come to use is nearly like the operation called the Schroeder-Hoffmeier method, but it removes more of the uterus and is more simple in the application of the sutures. So far as I am concerned, it is the outcome of my work and experience during the past thirteen years, and I am satisfied with it, though I hope to improve upon it.

There are four principal methods of removing the tumor and treating the pedicle. The intra-peritoneal,

[1] Read before the Boston Society for Medical Improvement, January 7, 1895.

first described by Schroeder; the extra-peritoneal, Koeberle and Pean; complete removal of all uterine tissue, first, I think, described by Eastman; and the method of vaginal fixation described by Byford. The method of treating these tumors by ligature of the uterine arteries from the vagina, recently proposed by Franklin H. Martin, must not be omitted, and bids fair to be useful. I have long ago given up the extra-peritoneal treatment by means of the wire and écraseur. It has always seemed to me unsurgical and clumsy. Indeed, in many cases it would be impossible to get the wire around the tumor until it had been enucleated, and by that time it would have been so nearly removed that one had better tie the uterine arteries than compress them by the wire, and cut off the tumor, sewing the peritoneum together over the stump.

Such a case I lately operated on in a woman fifty-eight years old. Her physician, Dr. A. D. Sinclair, had known of the presence of the tumor for eleven years, and she was sure it had increased in size rapidly during the past four months. The abdominal walls were thick with fat, and the tumor felt very elastic, more like an ovarian than like a uterine tumor. On opening the peritoneum the tumor was seen to be uterine, and could not be lifted out of the abdomen. It had grown from the posterior part of the neck and body of the uterus, and the intestines were incorporated with the peritoneum on its under surface and its upper end; that is, they lay in the peritoneum, which formed the capsule. There was no other way to get this tumor out but to make an incision through its peritoneal covering at its upper side and peal the peritoneum, with the intestines, back. In doing this the left ureter was laid bare for a large part of its length, and was carefully dissected from the tumor. If I had pinched up the tumor in the wire of an écraseur, I should either have enucleated it unintentionally or I should have included some part of the bowel or of the tortuous ureter in the noose. Or suppose that I had carefully enucleated the tumor before the application of the wire, I should only have had the neck left to be constricted; and how much more surgical, neat and dexterous to divide this, after ligature of the uterine arteries, and turn it out and cover the back of the stump with peritoneum, making the treatment of the stump extra-peritoneal, than to encircle it with a wire noose and transfix it with a long pin and straddle the abdominal wound with the pin, leaving the stump and the neck to slough away in two or three weeks, instead of having an abdominal wound with no break in its continuity. The convalescence is surprisingly rapid in many of these intra-peritoneal cases. In one case it was difficult to persuade a patient to remain more than two weeks after the operation. I am sure that the treatment by the wire écraseur will soon be wholly abandoned.

I prefer the intra-peritoneal treatment, so called, though it is really extra-peritoneal. The method which I follow in removing a fibroid tumor is the following: The patient is placed on a liquid and farinaceous diet for thirty-six hours before operation; the pubes are shaved; the abdominal walls are rendered aseptic by means of a hot bath, soap and water, ether and bichloride solution, and are covered with a bichloride-of-mercury dressing at least twelve hours before the expected time of operation, and this is changed immediately before the operation; the vagina is thoroughly douched with sublimate solution, after being mopped over with soap and water to get rid of the grease. The bowels are opened and the rectum thoroughly emptied. Everything to be used in contact with the patient or the operator and his assistants is thoroughly sterilized, and the patient is wrapped in a sterilized flannel suit made out of a large, thick blanket, either in one piece or in two pieces like pajamas. This was suggested to me by my *first* assistant, Dr. Edward A. Pease, and is one of the causes of success. It prevents any lowering of the patient's temperature, and keeps her warm during the operation and afterwards. I regard this as one of the important procedures in these cases. The legs and arms of the wrap are sewed up at the ends, and the abdominal portions can be tied together with tapes, and loosened and separated for the purpose of making the incision in the anterior abdominal parieties. There is no place for the external air to get in, except while the abdomen is open. As I have said before, this flannel garment has been sterilized, and so have the sheets, towels, ligatures, instruments, etc., used in the operation. The patient is placed in the Trendelenberg position. Indeed, without this position the intra-peritoneal removal of fibroids in a satisfactory manner would be almost impossible. The incision is now made of the required length and the tumor is delivered at once, if free from adhesions, by means of the corkscrew, or by any method of traction which seems most easy. A piece of gauze spread over the tumor is found very convenient in preventing it from slipping away from the hands of the operator. A large piece of gauze is now put in the abdomen over the intestines, and the sides of the incision above the tumor are often fastened together by catch-forceps or by a temporary stitch to prevent the intestines from protruding and to keep them clean and warm. The tendency of the bowels to protrude varies in different patients. In most cases the intestines lie still and quiet. In others they seem to leap out of the abdominal cavity whenever they get a chance. If in the process of lifting the tumor out of the abdomen adhesions are discovered, it is best to secure them in some way or to pass an elastic ligature around the neck of the tumor or of the uterus to prevent hemorrhage. This last procedure is rarely necessary, and I have never done it for this purpose.

When the broad ligaments are seen, I usually tie the left one first, passing the ligature low down and close to the uterus by means of Cleveland's needle, being most careful not to perforate the bladder; then I tie another ligature about an inch further away from the first towards the ovary and beyond the tube, or beyond the ovary and the tube, and divide between them. The tube, if left intact on the uterine side, prevents infection from a source to which the patient would be exposed if the tubes were opened. I leave the broad ligaments as long as possible, so that my seam over the stump when the operation is finished will be a short one. I do not care whether the ovary is tied off or not, nor do I necessarily remove it, for it is well supplied with blood from the ovarian artery, and will not slough when its uterine connections are cut off, and in fact, may be well enough nourished by adhesions; besides, if it remains, perhaps the physiological symptoms, which are often annoying after removal of the ovaries and uterus, the so-called "heat flashes," etc., may not occur if the ovaries are left. For the ovaries are the reigning powers in the generative organs. The expression

should be, "The ovaries and their appendages," not "the uterus and its appendages." The uterus and vagina are simply channels for the nourishment and passage of the ovum and fetus, the product of the ovary, and serve to expel the infant into the world. The vagina may be wanting or the uterus may be wanting, but their absence does not imply that of the ovaries. If the latter, however, are wanting, the other organs, I believe, always are.

I now go through the same process on the right side, and then make a circular incision through the peritoneal covering of the uterus in front about two inches above the outline of the bladder wall, which can usually be plainly made out by sight without passing a sound into the bladder, and the same distance above the rectum behind, the two incisions meeting on either side where the broad ligaments are tied, exactly as one would make a circular incision for an amputation of the thigh. These peritoneal flaps I then turn back, by the aid of this little spade-shaped instrument, which is a copy of a periosteum retractor in our case of instruments for cerebral surgery at the Massachusetts General Hospital, or else I use a duckbill-shaped blunt dissector, or my fingers. By not getting beneath the peritoneum into the muscular tissues of the uterus the separation is easy and bloodless, but if at all deep it is difficult and hemorrhagic. The uterus above the internal os in now denuded of its peritoneum and is ready to be divided. I then feel for the pulsation of the uterine arteries; and if I find them easily (and they are quite superficial), I tie them by passing a ligature of silk around them with an aneurism needle, each one separately; but if I do not feel them easily, or if there is a hemorrhage going on, from my flaps having been made too thick, I encircle the uterus at the denuded point with a strong, small, solid cord of rubber, and having tied it securely, I cut the tumor and uterus away, and later secure the uterine arteries at my leisure.

I now trim away the uterine tissue by a slanting cut in front and behind, the apex being at about the level at which the uterine arteries have been tied. I cauterize very thoroughly the uterine cervical canal at once, as soon as it is opened, with Paquelin's cautery. I always pass the point through the mouth of the uterus well into the vagina and allow it to remain there several seconds. A cauterization must be so thorough that the opening remaining will be large enough to act as a drain for the sloughing which always follows a hot iron, otherwise the external os may get occluded by the swelling (which naturally follows any injury to living tissues); and infection from the sloughing mucous membrane, might work its way back and contaminate the stitches by which the abdominal end of the stump is closed, and perhaps also the space lying between the stump and the peritoneum. One of the advantages of the closing of the peritoneum is that even if this blind space does get infected and an abscess is formed, the peritoneal cavity is not infected, and only a localized collection of pus is formed which may open spontaneously or be opened from Douglas's cul-de-sac. This I have never been obliged to do, though nature opened such an abscess for me once. There was good drainage, however, and with hot vaginal douches the trouble soon ceased.

Next I sew the muscular walls of the neck together by a continuous suture of silk over the cervical canal, so as to shut out the neck from the abdominal cavity. In sewing the sides of the stump together, it is important that the silk be put through healthy tissue and not allowed to pass through the tissue which has been cauterized, as this must slough away, and in this way the silk may get infected and cause an abscess or a discharge from the ligatures.

I then sew the peritoneal flaps together by a light continuous suture over the stump. I always use fine English braided silk, No. 4, for this suture I do not dare trust to the aseptic qualities of catgut. You will see that although this method is called *intra-peritoneal* it is really *extra-peritoneal*, even more so than the plan by which the neck is constricted by the wire and held outside the skin of the abdomen by a pin across the abdominal wound. I next turn my attention to the ovarian and round ligament stumps and tie the ovarian artery again separately. If the ovaries have been removed in whole or in part, I decide whether to remove them more completely or to leave them. There is now a sutured line running across the lower part of the pelvis, and, if there is no oozing, the abdomen is emptied of the sponges and pieces of gauze which have been put into it, the patient is lowered into a horizontal position, and the intestines descend to their normal place; the omentum is, if possible, spread over them and the abdominal wound is closed with silkworm-gut without drainage.

The flannel suit is left upon the patient for twenty-four hours or more, according as seems best and most favorable. The convalescence is like that after simple ovariotomy. The patient is generally up and about on the fourteenth day, and goes home by the end of the third week. This rapidity of convalescence is a great contrast to that following the treatment of the pedicle by the clamp. In the latter case convalescence is slow. The wire comes away sometimes as late as the third or fourth week, and the slough beyond the wire a week or two later; the abdominal wound is left with a depression at its lower part, which gradually, in the course of a month, fills up with granulations and rises more or less to the level of the surrounding skin. Something of the depression remains permanently, and this spot where the stump has come away, frequently becomes the seat of hernia.

I do not believe that there is much difference in the mortality between the extra- and intra-peritoneal (so-called) methods, success depending more on asepsis than on method; but if there is any difference, it would seem to be in favor of the so-called intra-peritoneal treatment. The whole success of these operations depends upon perfect asepsis combined with experience in abdominal surgery, a kind of surgery which cannot be taught, but must be learned.

During the last eighteen months I have removed 26 fibroid tumors by this method in my private practice. There has not been a single case of septicemia. One patient died twelve hours after operation, of shock, loss of blood from separated adhesions and diffuse nephritis (Whitney), the method of the operation having nothing to do with the result. All of the others (25 in number) recovered.

---

"The Health, Sanitation, and Climatology of the Southern States" is the title of a new quarterly journal devoted to sanitary science and medical climatology, and to a consideration of the health resorts of the Southern States. Edited by Walter C. Murphy, M.D., and published at Washington, D. C.

## REMOVAL OF THE UTERINE APPENDAGES FOR NERVOUS DISEASES.[1]

BY W. H. BAKER, M.D.

GREAT relief has come to the nervous diseases of women through the adaptation of asepsis in surgery by the gynecologist. This is the most apparent to those of us who had the trying experience of dealing with a class of cases vaguely described as ovaritis, pelvic abscess, or chronic cellulitis, and presenting physical conditions which were masked, indistinct, surrounded by the greatest uncertainty, and made apparently somewhat clearer at times by the greater prominence of an attack of localized peritonitis. Yet the primary cause of this same peritonitis remained surrounded by the greatest mystery.

That the theories advanced by Noegarath, in regard to the effect of gonorrheal poison on the tubes and ovaries, more than twenty years ago, should have been so slow in being impressed upon the minds of the profession and its tardy acceptance even then, is one of the gynecological wonders of the present age. Nor was it until the comparative safety in opening the abdomen was proved, that the acceptance of his theory was finally established. About the same time came the adoption of the idea of sepsis introduced from without, in the woman just delivered, as a cause of puerperal fever; and no one can forget the warfare in New York led to such a glorious victory by Dr. T. Gaillard Thomas.

With the frequency of abdominal sections for pelvic diseases the gynecologist was forced to admit the importance of tubal diseases as the cause of the recurrent peritonitis, which with its exudate had matted together the viscera in the pelvis resulting in the mass which had been considered chronic cellulitis. In other words, his touch, practised through the abdominal incision, separating adhesions and enucleating the mass, intensified by sight, both at the time of operation and in subsequent examination of the specimen removed, proved the fallacy of his previous theory and settled in his mind beyond a doubt the importance of the various diseases of the Fallopian tube, and their great significance in the subsequent rôle of pelvic inflammations.

The great help which the pathologist rendered in the clearing up of the vagaries of this subject came rather after the settlement of the facts in the mind of the clinical observer, and was given through his careful and thorough investigation of the parts removed and the frequent detection of structual changes in the tubes and ovaries which fully accounted for the observation of gynecologists and the sufferings of the patients. Nor is this surprising when we consider the infrequency with which death followed as a direct result of such tubal or ovarian disease, and that in such exceptional cases the matting together of the whole pelvic viscera, with possibly the abscess involved, and very likely the general peritonitis as well, all tended to mask the seemingly unimportant Fallopian tube. The condition of the patient in such cases was rather one of long invalidism and nervous derangement than of immediate danger to life. The means which nature provided in the plastic exudate, while protective in the matter of life, was too frequently the occasion of renewed suffering and nervous disease through its interference with the functional activity of the organs involved. That the working out of this problem of pelvic inflammation was not only the legitimate field of the gynecologist, but was developed step by step, must be recognized by all. It was his educated touch which, brought into direct contact with the diseased organs (generally at that time unseen until brought through the abdominal incision), that accomplished so much in the elucidation of pre-existing erroneous ideas. That the progressive stages which led up to the infrequent resulting death and the observations of the pathologist, were found by the gynecologist in the frequency of his operations and observations are perhaps expressed in degree from the first effort of nature to protect its vital peritoneal membrane in the sealing of the fimbriated extremity of the Fallopian tube to some part of the pelvis or the ovary on the one hand, to the extensive matting together of the pelvic viscera with a pyosalpinx as to its nucleus in the other instance.

When we consider the disturbance of nervous equilibrium so often produced by even the slightest change in the functions of the reproductive organs in women, we are prepared to accord to these organs the great importance which they exercise over the nervous system of the female during the period of menstrual activity. In verification of the fact, we have but to refer to the often-observed cases of delayed menstruation and the effect produced either through the suffering involved or the nervous excitability produced.

There is no definite stage or limitation of extent of inflammatory disease of the tubes or ovaries that marks a point where nervous disease shall begin or yet denote the character or degree of such nervous manifestation; it is rather a matter of nervous tolerance to the existing pelvic change, which must necessarily vary with the individual. It will be generally observed, however, that in those women of greatest nervous development and of the highest intellectual attainments there exists the least nervous tolerance to diseases of the uterus or its appendages. More especially is this true in such women as have not shown a corresponding physical development; or, again, in such as through sickness have had the physical strength impaired and have thus brought a greater strain on the nervous system.

Dr. T. Addis Emmet has shown, more than any one, the importance of cicatrical tissue in the vagina or cervix uteri as occasioning great nervous disturbances, and proved beyond a doubt that the latter was a result of the former in the ready disappearance of the nervous phenomena following the operation for the removal of the scar; and it is my opinion that this same sort of tissue on the intra-pelvic peritoneum as a result of inflammatory exudate is a not inconsiderable factor in occasioning serious nervous symptoms. That such symptoms have been usually ascribed to the distorted and fixed state of the ovaries and tubes I am well aware, nor would I underrate the importance of such in the production of such phenomena, but I would add the importance of the presence of the fibrinous product itself with all its contractiie tendency as a factor in itself, in the production of the nervous symptoms. When we see this self-same product deposited in the substance of the organ, whether it be the uterus, ovaries or tubes, and find in the later stages of the inflammatory process the cicatrical reaction having occurred, we then look for the greatest amount of bodily suffering as well as nervous symptoms; for in such a case we have the least degree of nervous tolerance to the diseased state on account of the greatly weakened

[1] Read before the Boston Society for Medical Improvement, December 10, 1894.

state of the nervous system through the long endurance of pain induced by the structural change.

The brilliant results which have recently been achieved in other parts of the body through the instrumentality of the surgeon, directed by the neurologist after the most careful study and close observation, are highly gratifying; and we would not have the same careful observer, in the field of nervous disease fail to apply his energies or recognize the importance of these pelvic factors in the production of nervous disturbances, even though they may be less serious or immediately alarming than the lesions of the brain. Let it be remembered that the delicacy which surrounds the pelvic lesion in the mind of the patient leads her generally to suffer without complaint, nor does she always realize that the suffering she endures is not the natural result of menstruation or child-bearing. Thus she is led to bear the extra strain with all patience until she is completely exhausted nervously, and a train of symptoms present themselves that can no longer fail to be recognized in their relation to the pelvic organs, or perchance the grave symptoms of melancholia are inaugurated. Can anything be more important than saving the reason of our patient? Yet who can tell how long she can endure the nervous strain from the suffrance of pelvic lesion to which reference has been already made?

Two things have led to much disappointment in the removal of diseased ovaries and tubes for the relief of nervous disease, namely, the expectation of a *too speedy result* after the successful performance of the operation, and the *postponement of surgical interference* until an amount of nervous damage has been done which is beyond power of relief.

In the first instance we must remember that the process of the pelvic inflammation is usually a slow one, recurrent in its tendency and often increasing in degree and intensity; thus it is only after months or years of suffering that the nervous system becomes so far impaired as to become, it may be, the prominent feature in the case. It is thus far too much to expect an immediate return to health nervously, after the recovery from the operation. What is to be claimed for the operation is rather a relief from physical suffering, and from the recurrent attacks of pelvic inflammation, thus making it possible for the nervous gain, which in its turn must be accomplished by a persistent carrying out of such rules and treatment as would be used by the physicians in any case of purely nervous origin.

Under this head we sometimes see cases reported as failures, which, taken soon after the operation, have shown very little nervous gain, or it may be by the increased nervous strain of the operation itself, show a worse condition nervously than before the operation. Yet the self-same case, if judged, one, two or even three years after the operation — due care and appropriate treatment having been given to the nervous system — we find in the full enjoyment of health. It not infrequently happens also that the very same means of nervous relief has entirely failed when adopted before the operation.

In the second instance, the physician is loath to advise the removal of the uterine appendages for nervous relief until the nervous disease itself is far advanced; and it too frequently happens that the consent to the operation is not obtained from the neurologist or the psychologist until an amount of damage has been done nervously or mentally which forestalls any hope of relief by *any* method of treatment.

I would not be understood by this, to advocate the too speedy resort to operation on the pelvic organs in nervous diseases of women, nor to support the wholesale ablation of the ovaries and tubes, which I fear has been practised in some sections of our country; but I would insist upon the resort to celiotomy, even if it were only as a means of perfecting our diagnosis in any doubtful case, in view of the frequency and importance of such sequelæ to pelvic inflammation, and I am sure from my clinical experience that the cause of such nervous disturbance will very often be found to exist in the results of a previously existing inflammatory process in the pelvic peritoneum. Of course, it is to be understood that in any such case the vaginal examination should give evidence of the existence of such pelvic disease before we should feel warranted in opening the abdomen.

Now let us turn to another view of our subject, namely, when some uterine or tubal disease exists which is the cause of various nervous manifestations, and for which the removal of the healthy ovaries is practised. This may be well illustrated by the existence of a small fibroid in the uterine wall. It is at once admitted that the presence of a fibroid does not usually occasion such phenomena; yet cases do sometimes occur where such a result is observed and where the location of the growth is such that its removal would only be practical by including the whole of the upper segment of the uterus in the operation. Now, if the uterus and fibroid together are not larger than the gravid uterus at the third month and the patient be thirty-five years of age or more, the removal of the uterine appendages, even though they be entirely healthy, will be found to be one of the surest means of restoration to health; and this with the minimum of risk to the patient.

We have undoubtedly noted the great degree of tolerance, both physical and nervous, in the majority of cases of moderately large fibroids, yet it is probably a fact that but few of us have noticed the exceptional cases of great nervous disturbance from the reflex irritation of a small fibroid of the uterus which is seemingly out of all proportion in its importance in the locality compared with that found by its presence in other parts of the body. This fact would be ascribed to its affecting an organ, the perfect performance of whose functions, influence in so great a degree the whole nervous equilibrium of the woman.

Again, in rare instances we find an undeveloped state of the Fallopian tube a cause of nervous disturbance. In such cases the symptoms are likely to be inaugurated at the time of puberty and to steadily increase until the patient becomes a nervous wreck.

Cases almost without limitation might be given in support of the foregoing, but this would be of little value except from a statistical standpoint. I desire, however, to give two or three illustrative cases.

### Results of Pelvic Peritonitis.

Case I. Illustrative of the effect of adherent tubes and ovaries on the nervous system.

Miss A. B., a Swedish woman, twenty-nine years of age, entered the Free Hospital for Women June 2, 1890. She was unmarried and had complained of severe dysmenorrhea for six years. This pain had steadily increased, and for five years she had been suffering from headaches before and after the menses.

Menstruation began at sixteen, and did not become regular until eighteen; was never very abundant, seldom using more than three or four napkins. She had always been a hard-working woman. Could obtain no clear history of gonorrheal infection. Entered the hospital as she was incapacitated for work one week out of each month, and therefore could not keep her place at service as a domestic.

Diagnosis was made of left retrolateral version of the uterus, with adherent tube and ovary to left pelvic wall; constriction of canal of uterus at os internum. June 12th, Dr. Kaan dilated the constriction of the canal with Hanks and Ellinger's dilators.

For three years after this operation her position was such that I saw her about her work repeatedly, and was often consulted by her about her condition. She was relieved from a certain part of the menstrual pain by the dilatation, but the headaches continued, and she grew irritable, wanting in patience, and finally suspicious of the motives of those about her, — at times quite irresponsible for her actions. All these symptoms were greatly exaggerated on the approach of a menstrual period. Longer delay of surgical interference was deemed unwise, and she was readmitted to the Free Hospital for Women May 6, 1893. I performed celiotomy, and removed both ovaries and tubes, which were found so strongly attached to the pelvic wall that the adhesions could not be separated with the finger, but I was obliged to cut them with the scissors. The bands of adhesion were large, strong and dense, requiring much time in their separation. The uterus was finally sewed to the anterior abdominal wall and the incision closed. She made a good recovery from the operation, and was discharged from the hospital May 30, 1893. From a period soon after her discharge up to the present time she has been employed in the families of friends or patients of mine, so that I am quite familiar with her condition. The headaches have entirely disappeared. She now appreciates that the people she is with are her friends and not her enemies; is happy and cheerful instead of despondent; loses not a day from her work, which is of an arduous nature. In other words, the result of the operation, now eighteen months past, is highly gratifying.

### INTERSTITIAL DISEASE OF THE FALLOPIAN TUBE.

CASE II. Illustrating the importance of the most careful search for disease of the ovaries or tubes in cases of long-existing nervous symptoms which have not yet yielded to the ordinary general treatment.

Miss M. J., an American lady, thirty-three years of age, consulted me April 19, 1889, on account of inability to resume her duties as a teacher in one of our public schools. She was highly educated and cultivated; her surroundings from childhood had been among the most intellectual people. She began to teach at a very early age, before she was seventeen, and had continued at that vocation ever since. She had broken-down nervously three years before consulting me, and had been in bed fourteen weeks at that time. Had the best of medical advice and care for her nervous gain. There was very little to point to any pelvic trouble, certainly nothing that might not easily have been explained by the nervous debility; such as a dragging feeling across lower abdomen on standing, or walking too far, relieved sometimes by lying down, and dysmenorrhea the first eight or ten hours of the flow. Her chief complaints were her inability to apply either her mind or body to any effort; constant depression, and apprehension as to her condition of health, occipital headache; inability to walk alone on account of dizziness; constant feeling of fatigue, more marked in the morning; want of sufficient sleep at night, often being awakened by a backache referred to the spine. She consulted me on account of the ineffectual result of her treatment, which for three years had been directed to her physical and nervous gain, thinking that possibly there might be some pelvic cause for her trouble. On making a physical examination, I found an anteflexion of the body of the uterus and endocervicitis present. The discharge from the endocervical membrane was highly irritating, causing abrasions of the epithelium about os uteri and to a slight extent about vulva and anus.

An anteflexion pessary was adjusted and an astringent application made to the endocervical membrane. These agents relieved in a measure the difficulty of standing, made it more possible to take longer walks and did away with a previously troublesome feeling of frequent action of the bowels, not loose in character, but formed, though of small amount.

For the next year every attempt was made by the aid of nervous tonics, massage, galvanism and rest to regain the nervous tone, but without effect. For the period of a few weeks the pessary was removed to see if its presence was preventing her gain, but she lost ground, and the annoyance of the frequent dejections returned and she could not stand or walk.

In February, 1890, a careful examination by the aid of an anesthetic revealed a thickened, cordlike feeling of the Fallopian tube on the left side, and an exploratory celiotomy was advised, not only by myself but by Dr. George L. Walton, who kindly saw the case with me.

This operation was performed April 14, 1890. Both ovaries and tubes were found free; a small cyst, the size of a marble, of the left ovary ruptured in removing. Left tube thickened and cordlike throughout its entire length; right one the same on proximal half. Both tubes and ovaries removed. The recovery from operation was uncomplicated, and she left the hospital May 20th.

The nervous symptoms continued, as previously described, after the operation for a year without being much of any abated. The second year she was able to take a place as night nurse at one of our hospitals; after that she had so far regained her strength, nervous and physical, that she was admitted as nurse at one of the leading training-schools of this country, where she remained two years and graduated; since which time she has been constantly employed in active nursing and feels quite equal to her duties. In fact, she has no complaint to make and considers herself perfectly well.

### INTERSTITIAL FIBROID OF THE UTERUS.

CASE III. Illustrative of a class of cases where the removal of the healthy ovaries and tubes is advisable for the relief of nervous symptoms occasioned by some uterine disease.

On May 24, 1876, I was called to see Miss L. H., who not recovering well from an attack of supposed threatened typhoid fever, but really of nervous exhaustion, and suffering considerably from backache, thought there was likely some pelvic explanation for her condition. She was an American, thirty-five years of age, her occupation a teacher in one of our higher

educational institutions of this city. She was a lady most refined and intellectual, possessing great capacity in her avocation. She had been unable to teach for five months prior to my visit, the prolonged strain of her duties having resulted in a complete giving out of her nervous strength. There had been no pelvic symptoms until within a very few months, even then not very distinctly marked, although on close inquiry, she admitted that for a year or two there had been slight dysmenorrhea the first day of menstruation. The menses were otherwise natural. Since being obliged to give up teaching, she had begun to suffer from occasional headache.

On making vaginal examination I found the uterus in the second degree of retroversion; otherwise the pelvic organs seemed normal. I replaced the uterus and adjusted a pessary; which I find from the record of the case, examined five months afterwards, held the organ in good position, and she was then able to take a good amount of physical exercise, but could not bear much nervous fatigue. She was advised not to resume her position as teacher for a year and to persist with her physical exercise.

In October, 1876 (the same year), she took a position as assistant nurse at the Free Hospital for Women, where she remained for about eight months and was enabled to perform the duties developing upon her most satisfactorily.

In January, 1878, she having in the meantime gone abroad with patients, having entire charge of them, I considered her physical condition so good that I removed the pessary, and three months later found the uterus in good position. Still the headaches continued, and seemingly were becoming more regular either just before or after the menstrual period.

For the next four years there were no special symptoms referrable to the pelvis, but the headaches increasing in frequency and severity ascribable to no definite cause, a vaginal examination was made under ether. This revealed a somewhat enlarged uterus, measuring three inches in depth of its canal, and thickened through antero-posteriorly on its left aspect. On account of the greater weight of the organ a pessary was re-adjusted, but had no effect in relieving the headaches.

In the fall of the next year, having dilated the uterine canal, under ether, I examined the uterus bimanually and found an interstitial fibroid growing in the left wall of the uterus, the organ being enlarged to about three times its natural size. The headaches were steadily increasing in severity, extending from occipital to frontal regions, and obliged the patient to give up entirely for a day when at their height, and required the greatest effort to keep about her work for one or two days more. She had never felt equal to resuming her duties as a teacher, but had continued those as nurse. When not suffering with a headache, she was able to accomplish a large amount of work, both physical and nervous. She consulted Dr. S. G. Webber and one or two other leading practitioners in regard to her headaches, but without avail. The suffering from the headaches increased correspondingly with the development of the fibroid.

In March, 1887, the fibroid had enlarged the whole uterus to a size corresponding to the gravid uterus at the third month. I again dilated the uterine canal, with the hope that the fibroid had become more submucous and that I might be able to enucleate it; but it was found that it had not changed its position relatively to the uterus.

By this time the headaches had become so frequent and severe that it was telling in a marked degree on the nervous strength of the patient as well as upon her general health. For two years before this period she was obliged to use morphia subcutaneously at the times of such headaches as the only means of relief, and this enabled her to keep about her work except for one day of each attack. The headaches did not come with perfect regularity, although she seldom escaped a menstrual period without one either just before or just after the flow; she would be subject to one or two attacks also between times. Nothing seemed to have any effect but the morphia, which was always administered subcutaneously by a physician. The various currents of electricity, massage, heat and cold, various drugs (almost without number) were all tried in turn, but without effect.

The patient was at this time forty-six years of age, and might ordinarily soon expect the menopause, but inquiry elicited the fact that her family almost without exception went to fifty-two or over, before the cessation of menstruation. It was therefore decided to remove the uterine appendages as a means of causing the atrophy of the fibroid, in the hopes that by the resulting change the headaches would be beneficially affected. The operation was successfully performed in May, 1887. There was nothing of importance to characterize either the operation or the recovery from it; all the organs removed looked perfectly healthy. In questioning her a few days since in regard to the immediate results of the operation, she mentioned the fact of which I had forgotten to speak, that is, the sense of aching, fullness and bearing down in the rectum which had been quite troublesome for about two years immediately before the operation, and which was never felt after the removal of the uterine appendages.

In regard to the headaches, it was a full year from the time of the operation before any good result was noticed. After the expiration of this time, however, the severity of the headaches diminished correspondingly with the atrophy of the fibroid and the uterus. One and one-half years after the operation the fibroid had diminished one-half. Three years after the removal of the uterine appendages the most careful examination could not detect any enlargement of the uterus; in fact, it was less than normal in size, and was in good position. For two years after the operation she was occasionally obliged to resort to morphia, to enable her to keep about her work. For the past five years she has not used it. She tells me that she still has a headache once in two to four months, but is not now obliged to give up to it, and that in its severity it is similar to the premonitory symptoms which she formerly suffered, but that there it stops and passes away with a night's rest. She considers herself well; and from my knowledge of the physical and nervous strain she has endured for the past four years, I should certainly say she is in a better state of health than most of us. As a summary of the foregoing I would offer the following:

(1) Disease of the ovaries or Fallopian tubes is sometimes an unrecognized cause of nervous disease.

(2) The adhesions resulting from attacks of localized pelvic peritonitis is a not infrequent source of nervous disease, either from the presence of the pseudo-membranes in themselves or from the interference

which they offer to the functional activity of the organs involved.

(3) The extent or form of the pelvic disease is no indication of the character or degree of the resulting nervous manifestation.

(4) A most thorough pelvic examination should be made with the aid of an anesthetic, in every *obscure* case of nervous disease in a woman, occurring during the age of menstrual activity.

(5) Some forms of uterine disease may occasion an amount of nervous disturbance, which may require the removal of the healthy Fallopian tubes and ovaries, as the simplest and safest means of cure.

## A CLINICAL AND EXPERIMENTAL STUDY OF THE LEUCOCYTOSIS OF DIPHTHERIA.*

BY JOHN LOVETT MORSE, M.D.

A GREAT deal of work has been done during the last few years on the subject of leucocytosis, especially in acute diseases. Diphtheria, however, has been rather neglected. As it is an acute disease with marked constitutional symptoms due to the absorption of the toxic products of bacterial growth, a leucocytosis is to be expected. The observations hitherto reported have shown this to a marked degree.

Bouchut and Dubroisay[1] in 1877 made repeated examinations of the blood by Hayem's method, in 84 children sick with diphtheria, and obtained 4,305,000 as the mean of 93 counts of the red corpuscles; that is to say, a moderate diminution, which was the greater the severer the sickness and the higher the fever. The white cells were, in the average of 93 counts, increased to 26,824, making the ratio of white to red equal 1 to 160. Bouchut gives the following summary regarding the frequency of the occurrence of the various numbers. The white corpuscles amounted to:

| | |
|---|---|
| 0 to 5,000 | in 1 case |
| 5,000 to 10,000 | in 11 cases |
| 10,000 to 20,000 | in 28 cases |
| 20,000 to 30,000 | in 19 cases |
| 30,000 to 40,000 | in 15 cases |
| 40,000 to 50,000 | in 7 cases |
| 50,000 to 60,000 | in 9 cases |
| 60,000 to 100,000 | once in every 10 cases |

The very high grade of leucocytosis reported by these observers seems almost incredible, but is probably to be explained by the fact that they used Hayem's apparatus, which does not compare in accuracy with the Thoma-Zeiss. It is also possible that owing to the lack of bacteriological examinations, there may have been some errors in diagnosis.

In a later communication Bouchut[2] reports the results of 177 observations in severe "septicemic diphtheria." He found an "acute leucemic" condition of the blood, which increased with the severity of the disease and diminished again with an improvement. He did not find this marked leucocytosis in the lighter cases, however. Hence he considers the examination of the blood as regards the number of the white corpuscles as of importance for diagnosis. No differential count of the white corpuscles was made in these cases, of course.

The only other examination of the blood in diphtheria which I have been able to find reported in an extended search through the literature of leucocytosis, is one by Reinert.[3] He studied one case in a twenty-four-year-old girl, where a blood examination was made, on account of an ulcer of the stomach, before the attack of diphtheria. His results were as follows:

11, xii, 3 P. M. Red, 4,772,000.
13, xii. Patient sickened with diphtheria with moderate fever.
16, xii, 3.30 P. M. Red, 5,050,000; white, 5,763; white to red as 1 to 870.
19, xii, 3.30 P. M. Second day after cessation of fever. Red, 4,398,000.
19, xii, 4.30 P. M. Red, 4,732,000; white, 7,700; white to red as 1 to 610.

That is, a slight increase of the colored elements was observed during the fever period, "which may be easily explained by the diminished ingestion of food and drink." There was little or no increase in the leucocytes.

As the results hitherto obtained were rather surprising and lacked confirmation, there seemed to be room for further investigation. Moreover, many points had not been studied, as the character of the leucocytosis, its influence on prognosis, and its relation to the membrane, glands, and complications. Through the kindness of Drs. Buckingham and Folsom I have been enabled to examine the blood of 30 cases in the diphtheria ward of the Boston City Hospital. Owing to the lack of time, in but one case was more than a single examination made. The presence of the Klebs-Löffler bacillus had been previously demonstrated in all of them, and none of them were complicated by other diseases, acute or chronic. The effect of the symbiosis with other bacteria was not investigated.

The blood was in every case taken from the lobe of the ear and examined with a Thoma-Zeiss apparatus. It was diluted 1 to 200 with a three-per-cent salt solution colored with methylene-blue, and the corpuscles in one cubic millimetre counted. Cover-slips were in all cases made at the same time, hardened by heat or benzine, and stained with Ehrlich's "triple-stain." A differential count of from 300 to 500 white corpuscles was then made, the classification recommended by Ehrlich being used. As far as possible, the blood was taken at the same time of day and between three and four hours after food. The condensed results of my work are appended in the accompanying table, which is arranged according to the day of the disease.

It is evident from the above table that diphtheria is accompanied by a very marked hyperleucocytosis, larger even than that found in pneumonia. This has become well marked by the third day, and is probably present earlier. In a general way it increases as the disease progresses, is greatest at the height of the disease, diminishes during convalescence, and disappears with or soon after the membrane. It also in a general way corresponds with the amount of membrane, varying with it directly. There are notable exceptions to this rule, however, as in Case VII, where the throat was full of membrane and only 8,000 white corpuscles were found, and in Case V, where there were 42,000, but only a moderate amount of membrane. There seems to be no evident connection between the glandular enlargement and the increase in white corpuscles. It is noticeable, however, that the fatal "septic" cases with greatly enlarged glands all showed a very marked hyperleucocytosis. Some of the mild cases, nevertheless, with little or no enlargement of the glands, showed just as much. The condition of the lungs and kidneys apparently had no influence in determining the number of white cells. It thus becomes evident that the hyperleucocytosis is not due to any symptom

* A paper to which was awarded the First Lyman Prize for the year 1894. This paper will appear in the Medical and Surgical Reports of the Boston City Hospital, Sixth Series.

or combination of symptoms, but is the result of some general influence which is present in every case. This influence can be no other than that of the toxines absorbed. Whether the individual variation is due to the amount of absorption, to some difference in the virulence of the toxine absorbed, or to some difference in the resistant powers of the person attacked, must, in the present state of our knowledge, be left unanswered. In the great majority of cases the increase was in the polynuclear neutrophiles, that is, the typical leucocytosis. In several, however, the proportions closely approached the normal. In a few, chiefly convalescent cases, there seemed to be a lymphocytosis; this, too, in cases without much external glandular enlargement.

The number of the erythrocytes was, with one or two exceptions, always somewhat above normal. The only patient in which they were diminished was a woman, evidently subject to a chronic anemia. I am unable to give any explanation of this increase.

This study establishes the fact pretty clearly, I think, that the examination of the blood in diphtheria as to leucocytosis is of no value in prognosis. For, although fatal cases have a pretty marked one, yet it is almost always present, and often very pronounced, even in the mildest cases.

Having thus established the existence of a leucocytosis in diphtheria, I will now take up briefly the various views with regard to the origin of leucocytosis in general, and later detail the results of some experiments in animals which I have made in this connection. I will take up the theory which seems to me most probable last, that of Goldscheider, comparing his views with the others in turn and quoting largely from him.

Von Limbeck [4] considers that leucocytosis stands in the closest connection with the formation of exudate, and considers it as entirely secondary to the exudation. He found that when the toxic products of microorganisms were introduced into animals a reaction followed which corresponded to the size of the dose; that neither blood nor other tissues reacted to small amounts; and that after larger, a local reaction and proportionate hyperleucocytosis occurred. A much more significant reaction of the tissues and a greater hyperleucocytosis followed when living micrococci were introduced. He concludes that the hyperleucocytosis arises from the development or presence of bacterial products in the organism, which have a further action on the white cells and bring them into the circulation. He does not explain what this action is, and expresses no opinion as to whether those cells are new-formed or merely driven out of the blood-forming organs. He nevertheless calls attention to chemotaxic action as probably playing a rôle in the process.

His theory must be considered as of little value, however, as he did not recognize the hypoleucocytosis which has been found by other observers. His failure to find this was undoubtedly because he made no examination under forty-eight hours. Moreover, other investigators, notably Goldscheider and Jacob, have produced a marked hyperleucocytosis by the subcutaneous injection of organic extracts without producing any swelling or exudate. These experiments evidently destroy the foundations of von Limbeck's theory.

Römer [6] as the result of his own and Buchner's [7] work concludes that the destructive products of dead bacteria or other cell-life, when introduced into the circulation, exert a direct formative action on the white cells, causing a new formation of leucocytes, exclusively in the venous blood. This increase arises through amitosis. He also claims that the cells found increased may in part be already present in the blood-making organs and be brought into the circulation by chemotaxic action. Rieder [8] and Löwit completely contradict his experiments and arguments while Goldscheider and Jacob find no difference in the blood of the veins and arteries and show conclusively that after a short time there cannot be. Their experiments show that there is no such thing as hyperleucocytosis in the veins alone, which could only occur as the result of a direct new formation of white cells in the circulating blood. Both Löwit and Goldscheider and Jacob deny that this takes place. They both find immediately after the hypoleucocytosis almost exclusively mononuclear cells. Gradually, however, during the course of the hyperleucocytosis, a decided preponderance of polynuclear arises. Goldscheider and Jacob also lay much stress on the fact that most of these cells are eosinophile, and hence consider that they are not entirely formed from the new mononuclear but are partly old cells which were lying in the bone-marrow ready for extrusion and have been brought into the circulation in increased numbers as the result of the chemical irritation of the injected material.

Löwit considers hyperleucocytosis to be entirely independent of chemotaxis, and believes that it is due solely to a previous impoverishment of the blood in leucocytes. He also believes that a hyperleucocytosis occurs every time after a part of the leucocytes have perished, because an increased influx of young leucocytes out of the blood-forming organs is thereby brought on, that is, hyperleucocytosis follows leucolysis, which may result from the presence of certain substances, as bacteriological products, in the blood. He found that in all cases immediately after the injection there was a decided diminution in the leucocytes, but that then a gradual increase took place, which developed as much more intensely as the previous diminution was great. Thus, according to Löwit, hypoleucocytosis and hyperleucocytosis are two processes which are inseparably connected, the second occurring as the result of the first and being impossible without it. Goldscheider and Jacob were able, however, by the use of repeated small injections, to produce a primary hyperleucocytosis. They also showed, by autopsies, on animals killed during the stage of hypoleucocytosis that the leucocytes were accumulated in the capillaries of the lungs and not destroyed. Löwit denies chemotaxis any part in the production of leucocytosis but recognizes, however, that he cannot explain how leucolysis causes such a marked discharge of young cells from the blood-forming organs. It is difficult to see on what grounds he can deny the influence of chemotaxic action upon this process.

Schultz [10] believes that in all conditions which are considered as hypoleucocytosis and hyperleucocytosis the white cells are neither diminished nor increased, but are merely distributed differently in the vessels. According to his experiments with protein and other injections there is neither a destruction of leucocytes — Löwit's leucolysis — nor an absolute increase of the leucocytes from the blood-forming organs afterward. That is, he believes that the hypoleucocytosis is merely due to the accumulation of the white cells in the central vessels with a corresponding diminution of those

in the peripheral, the hyperleucocytosis being due to the reversal of these conditions, the cells simply being differently distributed. Goldscheider and Jacob, however, found that the cells which accumulated in the capillaries of the lungs remained there, even increasing in number during the early stage of the hyperleucocytosis, thus showing that there is no shifting of the cells but an absolute increase. This increase is sufficient to counterbalance the first loss of cells from the general circulation and still far exceed the number normally there.

Goldscheider and Jacob[8] have performed a very large number of very careful injection experiments on rabbits, using extracts of various organs and bacterial products. Many of their results have been already noted. They made counts immediately after injection and then at frequent intervals. After injections into veins they found in one case a marked hypoleucocytosis in twenty-five seconds. On the average the hypoleucocytosis reached its minimum in five or ten minutes; then the number began to increase, the maximum hyperleucocytosis usually being reached in five hours, but often only after twelve to eighteen hours; the normal was again reached in twenty-four to forty-eight hours. After subcutaneous injections the results were the same, but slower in making their appearance, the minimum appearing in three or four hours, the earliest maximum in fourteen to eighteen hours. Autopsies on animals killed during hypoleucocytosis showed the capillaries of the lungs to be full of leucocytes; there were as many, or more, in them during the hyperleucocytosis. They also succeeded by giving repeated small injections, in producing a primary hyperleucocytosis. In other cases, by using very large doses, they caused death while the hypoleucocytosis still persisted.

Müller,[11] Everard, DeMoor and Massart,[12] and Canthack [13] have obtained similar results as regards hypoleucocytosis and hyperleucocytosis. Everard sums up his work as follows: The injection of bacterial cultures, living or dead, results first in a diminution of the circulating leucocytes, especially of those with multiple nuclei and granular protoplasm. When the animal survives the infection, the stage of hypoleucocytosis is followed by one during which the polynuclear granular cells are very abundant; then the blood resumes its normal characteristics. The hyperleucocytosis is not typical in cases which succumb to the injection, or may be entirely wanting in those which die quickly. Sometimes, when the infection is prolonged, it is replaced by a series of oscillations. Canthack made hourly examination of the blood after the injection of filtered cultures of vibrio Metchnikovi. He found, at first, during the rapid rise of temperature a marked diminution of the leucocytes which persisted until the pyrexia passed its climax. Four to six hours after the number was enormously increased, reached its height at the ninth hour, but persisted, though to a less degree, for forty-eight or seventy-two hours, or even longer.

As the result of their experiments, Goldscheider and Jacob conclude that the phenomena of leucocytosis are due to chemotaxic action. The first action is a repellent one on the leucocytes, and they are arrested and held in the lung capillaries, where they remain. The second is irritative — attractive — on the blood-forming organs, and the white cells already formed there are set free and an increased number of new ones formed and also set free. Some of these also are arrested in the lungs as the result of continued repellent action. There is no instant leucolysis, and the process is something more than a mere changing of leucocytes, without increase, from the inner vessels to the outer, and *vice versa*. They explain the hyperleucocytosis without hypoleucocytosis which occurs after small doses by the fact that the small quantity, being distributed throughout the whole circulating fluid is not sufficiently concentrated to exert an energetic enough repellent action on the leucocytes to cause much retention in the capillaries. If, however, such small doses are repeated at certain intervals, the positive, or attractive, influence gradually increases, finally becoming far superior to the negative influence which is exerted by these small doses. Thus the equilibrium between the two processes is finally destroyed in favor of the first, the result being a decided hyperleucocytosis. They explain death during the hypoleucocytosis by the continuation of the repellent action, the irritative action being so strong as to paralyze the blood-forming organs.

Several difficulties confront us when we attempt to compare the leucocytosis in man with that observed in animals. We naturally cannot subject a sick man to so frequent blood-examinations as an animal; and as the disease often extends over days and weeks, important changes may easily escape observation. Moreover, we almost never get a blood-examination in the early stage of a disease. However, the vast number of blood-examinations which have been made clinically during the past few years, have given us a general idea of the leucocytosis in most diseases. A hyperleucocytosis has been demonstrated in most acute infectious diseases, especially febrile.

A constant diminution has been found only in typhoid, malaria and puerperal sepsis. There is said to be a decided hypoleucocytosis in the acute infectious diseases where the patients die within a few days. This is certainly the case in pneumonia. I have not observed it in diphtheria, the only case which had a normal number of white cells recovering.

It is possible that there may be a primary hypoleucocytosis in man, but, as already noted, the patient is almost never seen early enough to demonstate this, if it exists.

It has been shown above, however, that it is possible experimentally to produce a primary hyperleucocytosis. Now the conditions in man are essentially the same as those in the experiments made regarding this point. For the ordinary method of infection is not by the sudden entrance of a large amount of toxic substances into the circulation, but by the continuous absorption of small quantities. Hence we expect a hyperleucocytosis without a previous hypoleucocytosis. If the infection be extremely sudden and severe and rapidly fatal, we have a condition analogous to that in animals killed by a very large dose during hypoleucocytosis. That is to say, the toxic material is sufficiently concentrated to paralyze the blood-forming organs. This would explain the fatal cases of pneumonia with no increase of white cells. Thus it is evident that the chemotaxic theory explains satisfactorily the leucocytosis found in man as well as in animals.

A series of experiments was made on animals to determine primarily whether the hyperleucocytosis observed clinically in diphtheria was due to the Kleba-

Löffler bacillus and its toxines or to associated bacteria. As far as I know, these are the first injection experiments ever made on animals with this bacillus or its products. At the same time a careful study of the leucocytosis was made, and the work of previous investigators in this line gone over. Autopsies were made in all cases and the organs examined.

Rabbits were used, as their ears naturally fit them for intravenous injections and the blood is easily obtained. The normal number of white corpuscles averages a little higher than in man. As there is a considerable variation in individual animals a count was made in every case before beginning an experiment. Rabbits offer the further advantage that they present no digestion leucocytosis.[10] The blood was always taken from the ear and diluted (1 to 200) with a three-per-cent. salt solution colored with methylene blue. The Thoma-Zeiss instrument was used, and the corpuscles in at least fifteen cubic millimetres counted. The differential counts were of 500 white cells hardened with alcohol and ether and stained with Ehrlich's "triple-stain." The toxines used were from a filtered bouillon culture which had been twenty-three days in the thermostat, and was preserved by the addition of one-half per cent. of carbolic acid.

I wish here to acknowledge my indebtedness to Dr. J. H. Wright of the Harvard Medical School for the use of the toxine solution, and to thank both him and Drs. Councilman and Mallory for valuable advice and assistance in my work.

## Clinical Department.

### OBSERVATIONS UPON CASES HAVING THE SO-CALLED "TÂCHES BLEUÂTRES" IN THE BOSTON CITY HOSPITAL.[1]

BY VINCENT Y. BOWDITCH, M.D.,
*Assistant Visiting Physician.*

SYNONYMS: tâches bleues, tâches ombrées, tâches ardoisées, tâches phthiriaques, maculæ ceruleæ, macules cyaniques, peliома typhosum.

ALTHOUGH reference to the literature upon this subject seems to indicate that the presence of these *tâches bleuâtres* is of little diagnostic significance in any case, yet their precise origin seems still to be a matter of some doubt, and hence a collection of the various theories upon the subject is of interest.

At one time these bluish spots, varying in diameter from the size of a pin-head to that of a fifty-cent piece, not disappearing upon pressure, and most frequently found upon the abdomen and flanks, during the course of typhoid fever, were supposed to be due to that disease. Slight allusion is made to them in Flint's "Practice of Medicine," under the head of Typhoid Fever, but no suggestion is made as to their causation. Trousseau had noticed them also in typhoid fever. Other observers found that the spots were not confined to typhoid, but noticed them in various other diseases: yellow fever, pleurisy, pneumonia, gonorrhea, and also in non-febrile diseases.

In 1868 Moursou, a pupil of Falot, and physician in the French navy, first advanced the idea that these spots were not the result of any one disease, but were due to the presence of pediculi pubis. Later, in quite an elaborate and careful paper, he gave his proofs of this theory, and as a result of his observations, makes the following statements:

Over 250 cases had been observed in every variety of climate and in diverse diseases, mild and grave. Delicacy of the skin, a blond complexion, and a phlegmatic temperament, he noticed, were the most usual accompaniments of the spots. He asserts that every time he found these spots the pediculi pubis or their ova were also present. He noticed, moreover, in healthy men who had had the parasitic infection for at least twenty days, that the majority of them had the *tâches bleues.*

Moursou's observations were so carefully made that one is certainly impressed by the probable truth of his theory, which has been substantiated by subsequent observers, namely, O. Simon, Gibies, Gebbin, notably by Duquet and Mallet. The former injected under the skin a paste made with the bruised pediculi and water, and spots similar to the *tâches bleuâtres* made their appearance. Mallet believes that the color is caused by the secretion contained in the thorax of the pediculus opposite the anterior pair of legs where there are two pairs of salivary glands, the contents of which are conveyed under the epidermis through the "haustellum" or sucking apparatus of the insect.

Most of the modern text-books in speaking of the *tâches bleues* seem to accept the theory of Moursou, notably Ziemssen, Strümpell, and Osler, although Osler evidently feels some doubt as to whether the mere presence of the pediculi is the cause of the spots, or whether there is not some accompanying condition of the patient which favors their appearance. He says: "If really caused by these parasites, it is difficult to understand why they should be present only with fevers," which implies that he has not met with them in non-febrile cases. An objection to the theory of Moursou was brought forward by some from the fact that the *tâches bleues* are sometimes found upon people of undoubted cleanliness of body, and of the highest moral character; an objection which would not in itself seem to be valid, because of the undoubted fact that such people have often by accidental means become infested by these insects, the presence of which can have been easily overlooked by the examiner.

In an article entitled "Blue Spots in Typhoid Fever," in the New York *Medical Journal* of October 20, 1894, Dr. A. V. M. Anderson, of Melbourne, Australia, is quoted. In the Australian *Medical Journal* of August 20, 1894, he writes that the "rash" is one of the least commonly seen in typhoid fever, and probably escapes observation on account of indistinctness. He found them in eight out of 915 cases. In five they were present upon entrance, the duration varying from five to fifteen days; in others they appeared on the fifteenth, twenty-first, and forty-second days, and disappeared usually in a week or ten days.

Dr. Anderson could find no evidence of the pediculi pubis, and had not noticed them on patients with other diseases. They were detected over the course of the subcutaneous veins, and would seem to indicate, according to Dr. Anderson, that they are due to an altered condition of the blood, which shows itself in the tendency to epistaxis in so many cases of typhoid. He regards them as of little clinical significance.

Still another theory is advanced by Professor Revilliod, of Geneva, for the purport of which I am in-

[1] This paper will appear in the Boston City Hospital Reports, Sixth Series.

debted to Dr. C. G. Cumston, who informs me that in a clinical lecture upon the subject, Revilliod stated that he believed the spots to be due to the *excrement* of the pediculus pubis, which he believes to be an insect of very cleanly habits, and that during the night he leaves his usual seat at the root of the hair, and deposits his feces in adjacent portions of the body. I have been unable, unfortunately, to obtain Revilliod's proofs either for this action on the part of the insect, or for his theory of the excrementitious nature of the spots; but it serves to show the diversity of opinion which still exists upon the subject.

Another theory which has been advanced is, that this insect has a special liking for the bodies of patients suffering certain diseases; but although they certainly seem to have been noticed more frequently in typhoid fever than elsewhere, as yet no substantial proof has been given that this fact is anything more than mere coincidence.

During my service in the last two years I have come across nine cases in which the *tâches bleuâtres* were present, and in every case the presence of pediculi pubis was proven. Three of these cases were typhoids, which recovered, and the others were one each of phthisis, jaundice from gastro-duodenitis, acute bronchitis, intermittent fever, hysteria, and the one which showed the most numerous spots being a fatal case of cerebral meningitis following an otitis media. Of these cases seven were males and two were females.

In Dr. George B. Shattuck's service this year up to the present, eight cases are recorded in which the blue spots were noticed, but unfortunately no record is made as to whether the pediculi were also present or not. In two which I examined I was unable to find the insect by most careful search, but in one of these cases I only made the examination on the day of discharge of the patient, who had been ill several weeks with typhoid; and in the other the patient had been transferred from the surgical ward as a possible typhoid case, having entered with suspected appendicitis, so that sufficient time had elapsed for the removal of possible pediculi before I saw the patients. The other cases, six in number, were all typhoids, which also recovered.

Judging by the frequency with which pediculi were found to be present in my cases, I can but feel that they would have been found in at least the majority of the other cases had special attention been directed to this point earlier.

Although from such a small number of cases nothing can be proven absolutely, yet they at least show that the spots can appear in quite a variety of diseases, and are not confined to either severe or mild forms of disease.

From this comparatively slight experience I am led to accept the view of Moursou as the correct one.

## Medical Progress.

### RECENT PROGRESS IN LEGAL MEDICINE.

BY F. W. DRAPER, M.D.

#### CADAVERIC RIGIDITY.

TISSOT has formulated some new views concerning post-mortem rigidity which differ from the theories previously promulgated by physiologists.[1] Most authorities have accepted the explanation of this phenomenon offered by Brücke and Kühne, that it is due to a chemical change, the coagulation of myosine; while others, following Ingsten and Brown-Séquard, regard it as a final contraction of the muscles and thus a physiological fact. Tissot's conclusions are as follows: (1) The rigid muscles can very often be electrically excited for a variable period after the advent of rigidity and even when it is completely developed. This persistence of excitability is almost constant in cases in which rigor mortis has supervened with rapidity. (2) The rigid muscles which have lost their electrical excitability often preserve their mechanical contractility for a considerable time. (3) The rigid muscles which have lost both their electrical and their mechanical excitability can still be excited to contraction by chemical stimuli. Contrary to the statements of several physiologists, the excitability of muscles to chemical reagents (chloroform, ammonia, ether, etc.) persists much longer than the mechanical contractility and is always the last to be lost. (4) Whilst the electrical excitability progressively diminishes, the excitability of muscles under certain reagents increases and reaches its maximum when that under electricity has disappeared and at the moment when the muscle becomes rigid. With some reagents, however, the reverse occurs and the diminution of the excitability is progressive. (5) Tetanized and fatigued muscles present an exaggerated sensibility to chemical reagents in the same manner as rigid muscles. This reaction has also been observed in muscles whose vessels have been ligatured for some time, and in muscles which have been submitted to the action of air, heat, drying effects, etc. (6) Contraction produced in rigid muscles by the action of some excitant, even if it be only a limited exposure to the vapors of chloroform or ammonia, is accompanied by the production of a "current of action" in the muscular fibres; it is also accompanied by the disengagement of heat, as in the contraction of living muscle. (7) Rigid muscles, when exposed to the air, give off carbonic acid and absorb

[1] Lancet, May 26, 1894, p. 1320.

oxygen. (8) In his experiments, Tissot was able only twice to cause the onset of rigidity in the gastrocnemius of a frog by a single strong electric shock, just before the moment when the muscle would have lost its electric excitability.

### THE COURSE AND EFFECTS OF BULLETS.

Victor Horsley recently presented an instructive paper before the Royal Institution, on the effects of modern small projectiles.[3] He said: "Some people seem to think that a small bullet at a very high speed will pierce the tissues of the body without doing much general damage. This, however, is erroneous. The bullet carries forward with it particles of the substance through which it is passing and thus practically becomes a larger projectile. If a bullet be fired through a book, it cuts out disks of increasing diameter as it traverses the pages. Hence, too, it is plain that the greater the sectional area, the greater the damage. As to the heating of the bullet, it has certainly been much exaggerated; and its effects in this direction, if indeed it has any, may be safely neglected. The physical constitution of a body has a most important bearing upon the behavior of a bullet entering it. Why does a bullet of a certain size and travelling at a certain rate, simply perforate some substances, such as wood or iron, while in others, such as clay, brain, etc., it exercises a bursting and disruptive action? The answer is quite simple: the destructive effects vary directly as the viscosity of the body. This was established by some remarkable researches on the effects of bullets on soft tissues made by Huguier, after he had observed the results of the wounds inflicted in the fighting in Paris, in 1848. He suggested, from observations made on certain dead organs, such as lung, that the reason of the great lateral disturbance was that the tissues contained water in large quantity; and that the energy of the moving projectile, being imparted to the particles of water, caused the dispersion of these in a hydrodynamic fashion. This suggestion was shown to be correct by Kocher in 1874–76. If a shot be fired through two tin canisters of equal size, the one full of dry lint and the other of wet, in will simply perforate the former, but will cause the latter to burst explosively. In the same way, shots fired into dough have more or less disruptive effects according to the percentage of water in the dough; and, in general, the more fluid the substance, the greater the destruction. Now, in life the brain is a more or less fluid body; hence, a shot fired into the skull must have a disruptive effect and tend to burst it."

### ABORTION INDUCED INSTRUMENTALLY BY THE WOMAN HERSELF.

Goenner[2] reports a case of a woman, thirty-seven years old, who had given birth to four children at term, and induced an abortion, without assistance, three times. Believing herself to be pregnant, she inserted an elastic catheter into the vagina. The operation caused considerable pain, and on withdrawing the catheter some hemorrhage occurred. It was discovered that a part of the instrument remained behind. An attack of peritonitis followed, and abortion occurred five days after the use of the catheter. Six days later, during defecation, the patient was seized with severe pain in the lower part of the abdomen and in the ileocecal region. No trace of the retained piece of catheter could be found by palpation and operative procedures were considered, when the missing fragment was passed in a fecal discharge. The vagina did not present any punctured wound. The patient eventually recovered.

### RIGOR MORTIS IN A FETUS.

At a meeting of the Edinburgh Obstetrical Society, December 12, 1894,[4] Dr. Ballantyne presented notes on a case of cadaveric rigidity in the fetus. The mother had not felt any movement for two days previous to labor, which was premature at six and a half months. The fetus at birth had the left arm sharply bent at the elbow, and on attempting to straighten it there was marked resistance and the biceps became very prominent. A similar condition was present in the right leg, which was bent at the knee. Two hours later, resistance could still be felt, but all signs of rigidity had disappeared the next morning. The reporter of the case reviewed the literature on the subject and had collected records of twenty-five cases extending over a period of forty years.

### TENACITY OF VITALITY IN HUMAN SPERMATOZOA.

Various authorities state that zoosperms may continue to move in the fluids of the seminal tract after death and for an indefinite time; the periods stated vary from twenty-four to eighty-four hours. Outside the body the movements of the spermatozoa have been observed for seventy-two hours by Hofmann, and Montegazza has seen them active four days after their discharge, the temperature being favorable. A case is on record in Beale's *Archives* in which active spermatozoa were found in the mucus taken from the vagina of a little girl fourteen days after she had been violated. And Mr. Piersoll[5] has recently published observations showing that zoosperms kept at a temperature of 8.5° C. will continue to show movements for nine days.

### BULLET-WOUND OF THE BRAIN, WITH SURVIVAL FOR TWELVE DAYS.

Cases of perforating gun-shot wounds of the brain in which the missile was extracted during the life of the patient, from the side of the head opposite to the wound of entrance, are certainly rare; and such cases terminating in recovery are still more rare. Dr. Tefft of Springfield, Missouri, reports an instance of unusual interest, which, though not ending in full recovery, has some extraordinary features. A healthy boy, twelve years old, was shot at short range with a twenty-two calibre revolver. The ball penetrated the frontal bone, seven-eighths of an inch above the upper margin of the left orbit and one inch from the middle line. A Nélaton probe dropped by its own weight through the brain a distance of seven inches as the boy lay on his back, the progress of the instrument being checked by the inner table of the occipital bone. Under antiseptic precautions, a disk of bone was removed with the trephine from the occipital bone over the point believed to cover the posterior end of the cerebral lesion. The operator was rewarded by finding the bullet at a point an inch and a half below the exit wound in the brain, and imbedded in the sub-

[6] Loc. cit., April 21, 1894, p. 495.

stance of the brain at a depth of from half an inch to three-quarters. Before the operation the boy was unconscious and had bled freely. After the removal of the slug, whose weight was twenty-three grains, the patient regained consciousness, was intelligent, ate, drank, talked, recognized his friends, and took an interest in his surroundings. The special senses were not affected. There was no paralysis. On the eighth day the boy was restless; his temperature rose; his pulse increased; his pupils dilated; he became apathetic. Coma developed, and he died on the twelfth day after his injury. A partial post-mortem examination of the wounded part failed to reveal any suppuration — the track of the bullet was still open. The immediate cause of his death was not determined.

### THE PHYSICAL SIGNS OF VIRGINITY.

An editorial writer in the *British Medical Journal*[1] so clearly states the need of conservative judgment in discussing this topic, that his words will bear repeating as a caution against dogmatism. After introducing his subject with the declaration that "the doctrine has come down to us from venerable antiquity that the hymen is the sign of virginity; its laceration the proof of defloration; its presence or absence the test of the virtue of an unmarried woman," the writer concludes his paper with these words: "It is clearly of the greatest importance that medical witnesses should exercise much caution in giving evidence in cases where the chastity of a woman is called in doubt. The presence or absence of a hymen is a mere matter of fact; but whether the law cares to admit it or not, juries certainly accept the evidence of experts as expressing not only a fact but an opinion upon it. Although, then, it remains true that in a small number, comparatively a very small number of cases, the signs of virginity may persist after carnal intercourse, and although it may be impossible by any one sign or fixed criterion to say that a woman is a *virgo intacta*, still it is often possible for a medical man, taking all the circumstances into consideration, to form an opinion which may be very useful to a jury in arriving at a verdict upon a case. It is not merely a question of a hymen, but of its completeness, its position, its thinness and its apparent lacerability under the asserted conditions; and, also, it is to a certain extent a question of these conditions themselves. A persistence of hymen which would be no disproof of rape by an old or feeble man, might, in the mature judgment of an experienced surgeon, be quite incompatible with sexual intercourse with consent. It might, however, be far better were medical witnesses to be appointed either by the judge or by consent of both parties, so as to do away with even the appearance of conflict between them [the experts]. This, however, we fear is at present but a counsel of perfection."

LIFE INSURANCE OF CHILDREN. — The Memphis Board of Health has sent a communication to the Tennessee State Board of Health, calling for such action as will lead to legislation prohibiting the insurance of the lives of infants and children within the State, on the ground that the practice leads to criminal negligence of children, and is to that extent prejudicial to public health. — *North American Practitioner.*

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. T. BOWEN, M.D., SECRETARY.

REGULAR Meeting, Monday, December 10, 1894, DR. C. F. FOLSOM in the chair.

DR. W. H. BAKER read a paper on

### THE REMOVAL OF THE UTERINE APPENDAGES FOR NERVOUS DISEASE.[1]

DR. J. HOMANS: From the title of the paper that was sent to me I did not expect quite such a paper as Dr. Baker has given us. I thought that his paper was to be on the effect on the nervous system of removal of ovaries and tubes. I took up my cases this afternoon to look through and got quite interested in reading a number of them, and I hope you will be also if you are not too much bored.

My first case I did about twelve years ago for what was called hystero-epilepsy, menstrual insanity. A doctor who was a relative of the patient wrote me about the patient and we concluded to operate.

I would like to say that my experience has not been like Dr. Baker's. I have had one or two very brilliant cases, but I never remove healthy ovaries and tubes for nervous disorder without the sanction and the support of Dr. Cowles or some equally high authority in nervous diseases. I will simply say that I operated on this young lady March 22, 1883. I found after I had operated that she had been in the habit of taking much more morphia than I had supposed. At any rate the ovaries and tubes were removed and we found the uterus very small. There was improvement in this woman for over a year so that the outlook seemed quite hopeful, but as soon as she got able to do something, being rather brilliant of mind, she began to write for magazines, and got money and purchased morphia, and went back to the morphia habit. She died in 1890 of consumption, seven years after this operation. I was present at the autopsy. The limbs were scarred all over with marks of the subcutaneous syringe. I could not see that the operation had been of any benefit.

The second case I operated on was at the request of the late Dr. Goldsmith. The case was reported by him in the *American Journal of Insanity*, and was really a brilliant case and complete cure, as far as the girl could be cured. I will read a little about her life:

The doctor gives a long account of the biography of the patient, as to the causation of the insanity, and thinks an accessory cause was eroticism. He asked me to remove the ovaries, which I did at the Danvers Asylum. She recovered rapidly. Was never unwell afterwards and her pain in her right side was less. She came home at the end of two months, and was entirely free from any attacks of insanity afterwards. She came to me about a year later with her mother, and I raised a little money with which she got a pony and peddled berries, etc. She was very gentle when I saw her on several occasions. She went on with peddling, and a few years afterwards died suddenly (of apoplexy?). That, I think, is a brilliant case, and it seems as if the removal of the ovaries and tubes was the turning-point.

[1] See page 224 of the Journal.

The third case was an insane lady. I operated at the request of her doctor, and I do not think it made any difference one way or the other. She was just as crazy afterwards as before, and died of phthisis a year afterwards at the Worcester Asylum.

The fourth case was a married woman of thirty-six. Pain and tenderness in the left iliac region ever since she can remember. In 1884 went to the Adams Nervine Asylum. She could do nothing at all when I saw her. She was almost bedridden, and had terrible pains, troubles and sufferings. In consultation with Dr. Chamberlain of Lawrence, I removed the ovaries and tubes in August, 1885. She continued menstruating with more pain than before, and in 1890 was still menstruating, her condition being no better and no worse.

The fifth case was very much like the first, a morphine-taker, single, twenty-eight. I operated in November, 1885. Dr. Tenney had the care of this woman. She was very hysterical, peculiar girl. I operated at Dr. Tenney's request, and with the idea that all her sufferings were very much increased at the menstrual period, and that her life was becoming a wreck; but I found that she was taking morphine to excess. Dr. Tenney reported that she was very much better afterwards, but I could not see that she was any better. She went to the Adams Nervine Asylum. In 1887 she was reported free from the morphine habit. I do not think the operation was of any benefit, and I did not have much faith in the doctor's statement that she was free from the morphine habit.

The sixth case was a single woman, thirty-six, a teacher, also a morphine-taker. She had insane impulses at times and great pain when unwell. I operated at the request of her brother, who was superintendent of an asylum. He promised me that after the operation she should have no morphine; but he and her sister gave her a little morphine, and gradually gave her more. She recovered entirely from the operation. I could not see that she was better or worse. She went to the South End, and was treated by a doctor with cocaine instead of morphine. Whatever she was treated with she died suddenly apparently of an overdose of some drug. Dr. Whitney made an autopsy, and found no cause for death unless it was toxic. She had also been at the Adams Nervine Asylum.

The seventh case was a single woman, twenty-eight. Ovaries and tubes removed for the same causes. Pain in the left groin, in the spine and in the back of the head. Thought to be worse at the menstrual periods. She was no better after it.

The eight case was another good case, a morphine case, the wife of a physician. Her left ovary was rather enlarged and lower than it ought to be. The left ovary and tube were removed. She gave up the use of morphine, gained in a year twenty-six pounds, looked bright and cheerful, and takes no morphine now. She has had her monthly turns once in three weeks instead of once in four weeks. The pain was probably relieved by the removal of the ovary and tube, and she gave up the morphine because she no longer needed it.

The ninth case was a single woman, twenty-eight. Ovaries removed on account of pain. Done in 1887. No better, no worse.

The tenth case was a married woman, no children. Better for a time, but I cannot see that she was permanently improved.

On March 5, 1892, I operated on a woman, thirty-two, single. Two years of continued pain and suffering, pain and tenderness of the left side. Uterus symmetrically enlarged, four times its natural size. The right Fallopian tube red and enlarged and two acute flexures in it. Right ovary and tube removed. That woman was very much improved.

Another was a pretty good one, and she also had been in the Adams Nervine Asylum before I operated, and I think she has been there again. She was the wife of a physician. She had erotic dreams. One of her hopes was that removal of the ovaries would take away that feeling. I operated in 1885, and found a fibroid tumor, some ascitic fluid, and the cavity of the pelvis filled to the brim by the fibroid which extended to the umbilicus. Both ovaries and tubes were removed. The fibroid disappeared in four weeks and could not be felt. She went away feeling remarkably well. She continued very much better for a number of years; went home and played whist and had parties, and was pleasant with her husband, but did not get rid of these erotic feelings. As time has gone on she has gradually become pretty feeble; and yet, on the whole, I think when we consider that the fibroid disappeared and she has had several years of comparatively good health, I think the operation was a success, but it did not absolutely cure her.

Another case was a young lady on whom I operated in 1891 for the first time. I removed the ovaries and tubes on account of menstrual agony, dysuria and pain at her earnest instigation; and it has not done any good to her pain. The menstruation continued, too, but I think the use of the catheter was not nearly so frequent. She went on with the pain, emaciation, debility, etc., and two years later I removed the uterus by the vagina. She has not the menstruation and the bladder symptoms are relieved, but the pain is just the same; so bad has it been, that last spring at her importunity I said I thought it would be an intelligent proceeding to open the abdomen and ascertain if there were any adhesions. I opened the abdomen, but found everything just as clean and healthy as could be. It was very interesting because I had removed the uterus from below. There was just a little pucker from the bottom of the pouch of the peritoneum where the uterus had been, but no scar. The wound was sewed up, and she was up in a short time; and her pain was just the same as before. I sent her to the mind-cure, and they did not seem to do any good. She has never contracted the morphia habit. Certainly the removal of the ovaries and tubes has not done any good in this case.

That concludes my experience in this subject. I thought Dr. Baker's paper was to be more on the cure of nervous disease by the removal of the ovaries and tubes. My belief in the efficacy of removal of healthy ovaries and tubes for the relief of nervous disease is very slight. I think it may once in twenty times perhaps, do some good; but I should never do it without the advice of some alienist in whom I had confidence.

Dr. R. T. Edes: If I had known how conservative were the views taken by these gentlemen I do not know that I should feel like saying anything. But I am confident I have met some surgeons who were not so careful to wait for the proof of some positive disease or some connection between the ovarian disease and the nervous disease. I remember a

few years ago some young man, I think of a small town in West Virginia, did something like one hundred more or less normal ovariotomies in the course of about a year. I am very much pleased to hear how conservative the profession here are. I should have remarked a short time ago that my field of observation was of a character not to show me anything like the proportion of favorable cases; but since hearing Dr. Homans's remarks my list comes nearer to his than I had thought it would. I have known of quite a number of these cases he has spoken of. I should coincide with him in his views in regard to a great many of them. I might speak in detail of one or two I have known something about. A case came under my observation some years ago, a lady physician, who had had her ovaries removed for what I have little doubt were hysterical symptoms, but which she thought were due to strychnine or something of that kind. Since then she has grown steadily worse, violently insane, and is now hopelessly insane at St. Elizabeth's. Before she was taken sick I got her to see a patient of mine who had a good deal of menorrhagia and a good deal of pain at the menstrual period, and she introduced a female physician from Philadelphia, and they were anxious to perform ovariotomy on this lady. I gave a qualified assent. She did not have it done at that time, and I got her to see Dr. Homans; and he, without absolutely declining an operation, spoke so doubtfully about it that she concluded not to have it done, and there were reasons why she could not have it done at that time. She did not have it done at all and got well. This family physician who had advised the removal of her ovaries had since had her own removed and was staying at my house when the second lady, then in comparatively good health, came to call upon her.

I took pains to get the history of some twenty cases, and several are those Dr. Homans has spoken of. I got at, as far as I could, the condition of the ovaries removed. I do not know how accurate it is. Sometimes they are spoken of as healthy, sometimes slightly cystic; others, cystic and indurated. Out of the twenty there is one person spoken of as a well woman. Dr. Webber told me the other day of a patient who had been under his care at the Adams Asylum. The case was evidently of hysterical character; quite a young woman. She had had her ovaries removed by Dr. Haven, and she was well. There are two cases, apparently, out of twenty-one.

The case Dr. Homans spoke of as menstruating with pain long after, and where he was doubtful as to her having got rid of the morphine habit, I did not at first recognize, because the doctor who gave me the account of it did not give me the name of Dr. Homans. Dr. Homans is right as to her not having improved very much.

Another case which Dr. Homans referred to I have noted as a death by cocaine. Another case, a patient, with hallucinations of many kinds, is still at the asylum, although she is going away to-morrow. I supposed when she came she had had large ovarian tumors which were removed simply on surgical grounds, but it seems the case was of this same class. I should say from the description of the case that the operation had given considerable relief.

A number of cases have applied for admission who have had the ovaries removed, and have been declined because we have got to look upon those cases as so hopeless; not that the operation necessarily makes them worse, although it has seemed to me that sometimes it has served to fix the condition. The truth probably is that the operation is not usually done except in cases already very severe and obstinate. Certainly our experience is that they are not a very encouraging class of cases.

There is one case on the list operated on by Dr. Baker a number of years ago. She was with us as a chronic invalid and I have heard from her as being in much the same condition. She menstruated with a great deal of pain and difficulty, but the pain was not quite so great as before the operation.

I should say that the removal of the ovaries was chiefly a surgical question, that the ovaries and tubes when diseased are properly subject to a surgical operation, but that the removal of the healthy ovaries was something which should be undertaken certainly very, very rarely. If cases like the second Dr. Homans spoke of were frequent, I should feel differently; but I do not think they are frequent.

I may add one word as to the absolute safety of the operation. One of our patients who suffered severely from hysteria and dysmenorrhea went, after suitable consultation, to a hospital where I suppose the surgery to be as good as is done anywhere in the world. She died of this operation in a week, apparently of nervous shock, there being no signs whatever of sepsis.

DR. F. H. DAVENPORT: I think it is a fact that the general consensus of opinion in regard to the removal of healthy ovaries and tubes for nervous symptoms is that it should be exceedingly rarely done. I think even those who are most ready to remove such organs for slight disease are very slow to do it where there is no evidence of any disease; and it seems to me the question comes to us most frequently in those cases where we find evidence of slight disease of the tubes or ovaries and where the nervous symptoms predominate to a very marked degree. The question here is, How far can we attribute the nervous symptoms to the slight disease we find present? And that is where I think the neurologist can help in those doubtful cases before operation, and an opinion should be obtained of some expert in nervous diseases so that both sides of the question may be fairly looked into. My own feeling about these cases is that, in the first place, all other methods of treatment which hold out a fair prospect of success should be tried — rest and local treatment and electricity, and various other agents which are employed; and if these fail and the symptoms are either confined entirely to the menstrual period or markedly aggravated at that time, that such conditions form a reasonable ground for supposing that, if artificial menopause is produced, good will result. It certainly is a fact that such nervous phenomena as we observe in connection with these cases are very rare after the menopause. They may in certain cases persist if present before, but as far as I know they rarely originate after the change of life. It would therefore seem reasonable to suppose that if the change of life is produced artificially, a certain amount of gain would result to the nervous system. I suppose that in some of these cases where operations are done for very slight pelvic disease, the mental effect *per se* of the operation is an important factor, and it is possible that in such cases a simple incision of the abdominal wall

without opening the peritoneal cavity would produce as good results as the complete operation; but it seems to me that conscientious surgeons would hardly practice a method so open to objection as that. In this era of abdominal surgery where exploratory operation is really so little dangerous and the techique is easily carried out so that the sequelæ that often used to follow can be avoided, it seems to me as if it were not such a serious matter in these doubtful cases to operate. Of course, the freedom from danger in operations of this character does act as a stimulus to doing the operation unnecessarily, at the same time it is not as formidable a procedure as it used to be; and it seems wise in these cases to give the patient the benefit of the doubt, and operate and remove the appendages if they seem diseased. I have had no experience with the removal of healthy tubes and ovaries, and I should feel very loth to do it; but in cases where there is some pelvic disease recognized by the abdominal examination and especially under ether, even though such disease may be slight, I think the operation might very reasonably be advised mainly on the ground of the nervous symptoms.

Dr. P. C. Knapp: My experience with patients who have had the ovaries and tubes removed as a cure for their nervous symptoms has been very slight, although I have seen, of course, a good many cases where the tubes and ovaries are removed on account of local disease. I never yet have advised such removal on account of nervous disease. I never yet have seen good results from it. I have seen the patient's condition rendered worse. Of course, there can be no question that when there is distinct disease of the ovaries and tubes leading to pain or other distressing symptoms which wear upon the patient's health, an operation should be done, that measures should be taken for the relief of the condition. I confess myself very doubtful about the cases of disease of the uterus or ovaries or any other organ of the body giving rise to nervous disease, which does not at the same time give rise to certain symptoms pointing to the organ itself. We may have, as we all know, referred pain, but the condition of a distinctly reflex neurosis from disease of an organ elsewhere in the body, giving rise to no distinct symptoms pointing to that organ, seems to me to be rather hypothetical. We have been through various epidemics of that we might say: one, which was advocated a number of years ago, was the treatment of spastic paraplegia in boys by circumcision, which I think has fallen into "innocuous desuetude." When it comes to the removal of healthy ovaries and tubes for the relief of nervous symptoms, I have still graver doubts. The recent investigations in hypnotism, the recent studies as to the influence of suggestion seem to me to explain the very few favorable results that have thus far been reported. Where you have advised a woman to undergo a surgical operation, which to her mind is a very profound and serious thing, where you have done a serious surgical operation, you have exercised as great and powerful suggestion as you well can. Dr. Davenport speaks of the operation in itself as not very serious. It may not be as a surgical procedure, but it is serious to unsex a young woman. I think it is evidence of a very distinct progress in medicine, this revolt against the indiscriminate spaying which threatened to cut down the western population. It has always seemed to me a little strange that although there is another organ similar to the ovary, with a similar or greater nervous supply, frequently the subject of disease, we have not yet had — although the fashion may come some time — castration of the male advocated as a treatment of nervous disease. It is very natural that we should seek every cause for hysteria and for general nervous weakness but the true one. People are very glad to find some foreign cause rather than to admit the inherited or natural weakness of the brain. Beside the ovarian pains of hysteria, we have as persistent pains elsewhere, and excision has never been recommended for any of those pains. The evidence, it seems to me, in regard to the treatment of hysteria and these extreme nervous conditions by removal of the healthy uterus and tubes is altogether insufficient to support the operation, and, as I have said, my experience in the few cases where I have seen it done has not led me to favor it.

Dr. M. Prince: I understood that Dr. Baker's paper was to be on the removal of healthy ovaries and tubes, and not of diseased ones; and therefore it is with an apology to Dr. Baker that I say the few words I shall say, because they will have no bearing at all upon his paper. Regarding the removal of diseased tubes I do not desire to express any opinion at this time. I have a very strong and decided opinion on the question of removal of healthy ovaries and tubes. I do not doubt that there occur occasionally exceptional cases, cases which have taxed our ingenuity and our patience, cases in which we have tried everything and are willing to do almost anything, and I can conceive that in such a case I might be tempted or it might be justifiable to remove healthy ovaries thinking it might somehow or other remove the symptoms; but I believe, as Dr. Homans has said, and as Dr. Edes and Dr. Knapp have said, that such cases are very few, are exceptional, and even though the operation should be advisable I do not believe it is because there is the slightest connection between the healthy ovary and these nervous symptoms; nor does a successful issue show that the healthy ovary has anything whatsoever to do with the production of those symptoms. The same story has been repeated over and over again in connection with epilepsy. For epilepsy we have had every kind of operation suggested; for instance, to only mention a few, tying of the carotid, tying of the vertebral, castration, removal of the ovaries, trephining the skull simply, and so on, and yet all these operations have fallen into "innocuous desuetude," notwithstanding that some of these operations have had most brilliant results, as brilliant as any reported to-night, and yet we all know that epilepsy is not in any way connected with those parts which were the seat of operation. I dare say we may get successful results in the relief of nervous symptoms by the removal of the ovaries, but it is also true that those same results could probably be obtained in any particular case by any other operation. I believe with Dr. Knapp that when those results do occur they can be explained in a certain number of cases by suggestion, and in other cases, if not by suggestion, by some profound physical effect on the nervous system which could probably be produced by any operation such as the amputation of a toe; and if it comes down to the question of the removal of a toe or removal of the ovaries, I think it might be decided in favor of the ovary and to remove the toe. One reason why I speak somewhat strongly is because the operation itself is founded upon a wrong pathology of nervous disease. The latest researches that have been made, es-

pecially the researches made in France, have shown that our knowledge of hysteria in particular must be completely revised. We have learned much regarding this disease. That the origin of hysteria is not in a healthy uterus or ovary, of course, has long been known, notwithstanding the temporary popularity of the removal of these organs. But, more than this, it is evident that we must look for the origin of hysteria in the brain or mind itself and not in irritation from distant parts; in many cases, at least, in certain fixed ideas, or in fixed morbid nervous processes which do not rise perhaps as high as ideas. Certainly the origin of many of these symptoms is not in the uterus, but in the mind itself.

The last case which Dr. Homans reported, that of a woman complaining of pain, was to me a typical case of what might be called subjective as opposed to objective pain. I believe the pain in that case arose in the patient's brain, from an association of processes there. This ovarian pain is one of the most common symptoms in nervous prostration, and has nothing to do with the ovary. I believe it arises from its connection with central processes and not peripheral processes, and when it is cured by operation it is by the profound effect on the system by suggestion and not by the operation *per se*.

DR. BAKER: I feel very glad to be so strongly assured by the remarks of the several gentlemen that the healthy ovaries and tubes of our women in this locality are so carefully guarded. I am sure that it is as it should be. There is no danger in this locality of our being so strongly criticized as some other places have been in regard to the wholesale manner in which the ovaries have been lost.

Before reading my paper I made an apology for the title. I am very glad indeed that the title proved a little misleading, in that it called out such a remarkably interesting series of cases as those presented by Dr. Homans, and also the remarks of some of the gentlemen present. I also thank you, Mr. Chairman, and the Society that an indulgence was granted in that the lines of the discussion were not drawn too rigidly and that the subject under discussion was broadened to take in the question of the removal of the healthy ovaries and tubes as well as those considered by the subject of the paper itself. I desire to thank the Society for the interest shown in the paper.

## Recent Literature.

*Blood-Serum Therapy and Antitoxins.* By GEORGE L. KRIEGER, M.D., Surgeon to the Chicago Hospital, etc. Chicago: E. H. Colegrove & Co. 1895.

The purpose of this little book is to present, in a readable form, the present state of our knowledge of the subjects which constitute its title, and an account of the experimental work upon which this knowledge is based. This has been fairly well done, although some recent important work receives no mention. A book of this kind has only a transient value in these days of rapid advance in our ideas concerning infection and immunity, so that when it reaches the readers' hands it may be already behind the times. A few reproductions of micro-photographs of bacteria are included.

THE BOSTON

# Medical and Surgical Journal.

THURSDAY, MARCH 7, 1895.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.*

*Remittances should be made by money-order, draft or registered letter, payable to*

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

## THE ABORTIVE TREATMENT OF ACUTE BRONCHITIS.

WE are indebted to a French therapeutist for the knowledge of how to *abort* an attack of acute bronchitis. Dujardin-Beaumetz in the last number of his *Bulletin de Thérapeutique* formulates this treatment in these terms: "Massive doses" of tincture of aconite twice a day. Be sure your subject is a vigorous adult, then give him twenty-drop doses night and morning of the strong tincture of the root!

We are advised to continue "this medication" for eight days! This is the "abortive" treatment of acute bronchitis!

Just on what principles these large doses of this powerful narcotic are supposed to act in breaking up a bronchitis, the distinguished writer does not inform us. We have been taught to regard aconite in such doses as an energetic spinal, cardiac and vaso-motor depressant. Good authorities, as Brunton, Stillé, H. C. Wood, Ringer, recommend small doses often repeated. Even Dujardin-Beaumetz admits that the large amounts may do harm, and that susceptible persons have died from the effects of such massive doses as he recommends. Therefore we must first be sure that our patient has no unusual susceptibility to the drug.

But seriously, it may be asked on what principle aconite given in any dose does good in a cold or in a bronchitis? And perhaps it would be difficult for even the enthusiastic prescriber of the drug to give a perfectly satisfactory answer. He would probably say that he gives aconite from empirical considerations. It might be alleged, too, that aconite slows the pulse, lowers the temperature, quiets the nervous system and so benefits the patient. Dr. Fleming's conclusion, from a consideration of the action of this drug on the circulation, is that it is a medicine of great value in all cases where there is inordinate activity of the circulation; it lowers the arterial tension, and so diminishes the flow of blood to the part. Many think that this is

not absolutely demonstrated. Ringer says that aconite causes capillary congestion. Cold does the same. Aconite cures because it depresses the vaso-motor system, and hence lowers the excitement of febrile reaction. But in order to accomplish this the dose should be small and frequently repeated, so as not to allow any secondary wave of reaction. Large doses produce too powerful a shock to the nervous system, and the ensuing reaction is intense; any therapeutic gain is bought at the expense of too much prostration.

These considerations, whether entirely well founded or not, have influenced great numbers in the profession. Aconite is still given largely in bronchial complaints but in small doses.

It is still regarded by many, for empirical reasons, as almost specific in acute inflammatory throat troubles. It would not, however, be difficult to show that the number of practitioners who put much confidence in this old remedy, and prescribe it habitually in throat and broncho-pulmonary affections is a constantly *diminishing* quantity. It does not figure largely among the standard medicines in the principal hospitals, while ipecacuanha still holds its own, at least in infantile therapeutics.

. Doubtless the present views, becoming generally prevalent, relative to the microbian origin of even the common bronchial catarrhs (see JOURNAL, 1893, No. 21, p. 522) are doing much to influence the choice of remedies in these affections. It seems now most probable that the first step in the series of morbid changes resulting in bronchitis consists in a disorder of the vaso-motor innervation which causes congestions and places the organism in a state of lessened resistance; and just in those localities where microbes are normally present we see inflammations set in of microbe-origin which are truly infectious, though non-specific.

If this view be correct, remedies are to be sought which shall improve rather than lower vaso-motor innervation on which the inflammatory changes so much depend. Alcoholic stimulants, quinine and strychnia are prescribed with some reference to this end. Alcohol and quinine at the same time promote the peripheral capillary circulation, sustain the heart, and so oppose congestions in foci of least resistance. A hot diaphoretic drink at the onset of the cold, and rest in bed may do much to abort a bronchitis. The benefit accruing from rest and general warmth is too obvious to require comment.

## CRAIG COLONY FOR EPILEPTICS.

THE Annual Report of the Board of Managers again draws our attention to this institution, the second one of its kind to be established in the United States, and also to the subject of State aid for this class of unfortunates. Ohio was the first State to take definite measures towards the establishment of a separate State institution for epileptics, and in 1890 passed a bill authorizing the appointment of a committee to select a site and to contract for the erection of buildings for this purpose. This institution was placed at Gallipolis, and is now known as the Ohio Hospital for Epileptics.

An act "providing for the appointment of a commission to locate an institution for epileptics in the State of New York" was passed in 1892. This commission selected an estate of a little more than 1,850 acres near Mt. Morris, in Livingston County; and in 1894 the legislature appropriated $140,000 for the purchase of this property, for its protection and care, and for the renovation of the buildings already existing, so as to render them suitable for the reception of patients. This property has now been purchased; and the buildings, with some alterations and repairs, will accommodate at least 300 epileptics. The institution was named "The Craig Colony for Epileptics."

The managers desire to admit inmates to the institution in the spring, and ask for the sum of $25,000 for the maintenance of 100 patients. The estate requires that indigent persons shall be received into this colony, and paid for by the State at not more than $250 per annum for each patient, and persons so paid for shall be known as State patients. The board proposes to build this year five buildings — an administration building, two observation cottages, and two hospital cottages. On admission to the colony each patient is at first to be sent to an observation cottage, so that he can be watched for a time until his exact condition has been ascertained, and he can be properly classified and assigned to the building most suited to his requirements. The importance of the proper classification of epileptics is thus almost for the first time practically acknowledged in this country; and in this a great advance has been made, both for the study of the disease and for the care and cure of the patients.

The demand for the establishment of State institutions for the care of epileptics in the more densely populated States is very great. In the State of New York the number of epileptics is estimated at 12,000, of which about 400 are in the insane asylums and about 600 in the county poorhouses. In Massachusetts last year there were rather more than 300 adult epileptics in the asylums and almshouses.

We cannot better express the claim of this class to public care and sympathy than by a short quotation from the report: "The State now makes provision in separate institutions for the insane, the blind, the deaf and dumb, and others suffering from chronic maladies. All these unfortunates are proper subjects for State care, but not more so than the epileptics, for whom nothing has been done. At present the epileptic, if he is in indigent circumstances, is sent to the poorhouse, where his condition rapidly becomes worse. If possessed of means, he remains among his relatives and friends, a constant source of worry and trouble to them, and constantly undergoing mental and moral deterioration. Whether rich or poor, he is shunned and feared by all who do not consider themselves responsible for his welfare; and he is in many respects more an object of sympathy than either the blind or the deaf and dumb."

## RESULTS OF ANTITOXIN TREATMENT.

IN a book which has recently appeared under the title "Diphtheria, Croup, Serumtherapie," Escherich, of Graz, gives his experience with diphtheria antitoxin. Out of 87 cases of diphtheria he had employed the antitoxin in 51, that is, in all the severe cases; of these, five, or 9.5 per cent., died. This percentage is diminished to 3.8, if three cases which were moribund when first seen are not counted. The total mortality from diphtheria at the time the serum was employed was 9.2 per cent. Leaving out the three cases alluded to above, this became 4.5 per cent., thus giving 95.5 per cent. of cures, a percentage which he had not been able to approach during a long service at the Children's Hospital.

Escherich divides his cases into three classes: (1) localized diphtheria; (2) progressive laryngeal diphtheria; (3) septic diphtheria. Of these the second form was most favorably influenced by the serum treatment. The most important effect of the antitoxin, according to Escherich, lies in the influence on the local process, in the rapid separation, and prevention of spreading of the membrane. Less evident is its effect on the toxic symptoms.

The serum treatment must be begun as early as possible. Escherich makes the statement that the mortality of cases of uncomplicated diphtheria, brought under treatment within the first three days of the disease, and treated carefully and intelligently by antitoxin, can be reduced to zero. As to unpleasant after-effects, he noted in three cases an eruption appearing twelve to fourteen days after the injections, complicated in one case by fever and pain in the joints.

## MEDICAL NOTES.

PROF. E. L. RICHARDS ON FOOTBALL. — Prof. E. L. Richards, of Yale, contributes to the March number of the *Yale Medical Journal*, an article on football, which should be widely read, especially by those who inveigh so fiercely against the game.

SMALL-POX AT HOT SPRINGS, ARK. — An epidemic of small-pox has broken out at Hot Springs, Ark. Forty-two cases are reported to have occurred. A house-to-house vaccination is being made, and other precautionary measures taken. The authorities report that they expect to have the epidemic under control within a short period.

TREATMENT OF DIPHTHERIA WITH ANTITOXIN. — Dreyfus (*Lyon Médical*, 1895, No. 5, page 146) relates that from October 15, 1894, to January 21, 1895, 78 cases of diphtheria were treated with the antitoxin at the Charité Hospital of Lyons. Among this number there were 15 deaths, a mortality of 19.29 per cent. Five of the deaths were due to conditions of which the diphtheria was a complication, one to typhoid fever, one to pneumonia, one to diarrhea, and two to broncho-pneumonia. In previous years the mortality of diphtheria has been 50 per cent.

SPONTANEOUS FRACTURE OF RIBS. — In the *British Medical Journal* for January 12th, a case was reported of spontaneous fracture of the eighth and ninth ribs in an anemic woman just previous to the onset of labor. John Freeland, government medical officer at Antigua, West Indies, reports two other cases in a letter to the same journal. One occurred during a severe paroxysm of coughing, and the other during a severe labor pain. The last case occurred in an unusually muscular woman, the eighth and ninth ribs on the right giving way with an audible report, being broken undoubtedly by the action of the powerful abdominal muscles.

TUBERCULOSIS OF THE PLACENTA. — Lehmann (*Berlin. Klin. Woch.*, 1894), reports from the Obstetrical and Gynecological Clinic of the Charité Hospital in Berlin, a case of importance with regard to the transmission of tuberculosis from mother to child. On examination of the placenta from a mother suffering from chronic tuberculosis of the lungs and larynx, he found a large tubercular focus in the chorion. In a villus which projected into this tubercular mass he found a few tubercle bacilli. The child of this tubercular mother died on the tenth day, and at the autopsy no evidence of tuberculosis was found. In a case previously reported a large tubercular focus was found in the decidua.

### BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, March 1, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 44, scarlet fever 47, measles 55, typhoid fever 2.

INCREASED SALARY FOR CHAIRMAN OF BOSTON BOARD OF HEALTH. — The salary of the Chairman of the Boston Board of Health is to be increased from $3,000 to $4,500. This is an act of simple justice and at the same time of real economy. An incompetent commissioner of health is dear at any salary; on the other hand, for the services of an experienced sanitarian who must at the same time be an independent, impartial, intelligent judicial and executive official, the larger salary is really small. For many years Boston has enjoyed the advantages of such combined service from Dr. S. H. Durgin. We doubt whether there is another department administering the city's affairs, in regard to which as little adverse criticism has arisen as in regard to the Board of Health during the last twenty odd years; and yet there is no department in which mistakes might more easily be made, and none in which mistakes would be likely to entail more serious consequences to the community. We are glad the city government is disposed to show appreciation of Dr. Durgin's past services to the city and to retain the benefit of his experience for the solution of future problems.

The wise administration of the sanitary affairs of a big, modern city is no small problem.

The Boston District Nursing Association. — The annual meeting of the Boston Instructive District Nursing Association was held at the home of Mrs. William Appleton, 76 Beacon Street, on February 27th. Twelve nurses have been maintained by the association, each having a district under her charge. These have attended the various dispensary physicians on their rounds, and have had charge of the outdoor relief department of the Children's Hospital. Addresses were made at the meeting by Dr. Charles L. Scudder, Dr. John W. Bartol and Rev. John S. Lindsay, D.D., who thanked the association for the valuable service its nurses were performing in educating the sick poor to an understanding of better methods of life. The following-named officers were elected: Miss Phœbe G. Adam, President; Mrs. C. P. Donald, Secretary; Mrs. Otis Norcross, Jr., Treasurer.

Bovine Tuberculosis. — The Joint Committee on Agriculture and Public Health of the Massachusetts Legislature, which has in charge the matter of the suppression of bovine tuberculosis, is reported to have agreed that the cattle commission is to be granted $150,000 for the completion of its work, instead of the $212,000 asked; that the farmers are to receive as compensation for tuberculous cattle the full value of a healthy animal; that the State shall pay all quarantine expenses after seven days, and also pay for all carcasses condemned as tuberculous at the slaughter-house. As the cattle are ordered to quarantine by local inspectors not responsible to the State commission, and as owing to the smallness of the appropriation the force of the commission will have to be reduced, so that it will be impossible to make all tests within the seven days of quarantine at the farmers' expense, it is feared that if this bill becomes a law, it will result in very heavy expense to the State. With regard to paying for tuberculous carcasses at the slaughter-houses, what reason is there that the State should pay for them, any more than pay for other food unfit for use? And what has the payment by the State for meat condemned as tuberculous to do with ridding the State of tuberculosis among live cattle? Surely this bill, if passed, will be framed to give the farmers and cattle-owners something for nothing, — in fact, pay them for allowing the favor to be done them of purifying their herds. It would be a profitable business for farmers to import tuberculous cattle purchased at their real value outside the State and sell them to the State for ten times their real value!

## NEW YORK.

Influenza in New York. — During the week ending February 23d, 42 deaths from influenza were reported in New York, and in the week ending March 2d, 32.

Dr. Jenkins Appointed Special Pathologist. — At a meeting of the Board of Coroners held March 2d, Dr. Wm. T. Jenkins, recently Health Officer of the Port, was appointed special pathologist to the board, without salary. His duties will be to assist in making autopsies when requested, and it is stated that Dr. Jenkins had offered his services gratis.

A Gift to the Montefiore Home. — The Montefiore Home for Chronic Invalids has received a gift of $25,000 each from Messrs. Jacob H. Schiff and L. G. Bloomingdale for the founding of a country branch for the reception of patients suffering from the early stages of pulmonary tuberculosis.

Roof Gardens for the Poor. — At a recent meeting of the Board of Aldermen a special committee, consisting of the standing Committees on Police, Health and Docks, was appointed for the purpose of investigating the subject of roof gardens for the poor on the river docks. They were requested to recommend to the board at an early date what number of such gardens should be erected and to introduce such resolutions, ordinances, etc., as will carry the project into effect.

Transfer of Dependent Insane from County to State Care. — A bill, which seems likely to be passed, has been introduced in the Legislature at Albany having for its object the transfer of the dependent insane of New York County. This measure, which, it is understood, emanates from the State Charities Aid Association, provides that the New York City asylums for the insane, located on Ward's Island in East River and at Central Islip, Long Island, shall be transferred to the care and custody of the Manhattan State Hospital, to be established by the act. The whole of Ward's Island, with its buildings and the equipment of the existing asylums, is to be leased to the State at a rental which is to be the equivalent of interest at the rate of 3 per cent. upon the sum of $2,500,000. The Central Islip property is also to be leased to the State at a rental which shall be the equivalent of the interest of 3 per cent. upon $400,000. It is provided that either of the leases may at any time be surrendered by the State, or may be terminated by the city, by five years' written notice to the comptroller of the State.

The Manhattan State Hospital. — The Manhattan State Hospital is to be governed by a board of seven managers, appointed by the Governor and confirmed by the State Senate, and their powers and duties shall be the same as those of the managers of the other State Hospitals. The Commissioners of Charities and Correction of New York City are to surrender the lands and buildings of the existing asylums, with their furniture, fixtures, stock and supplies then on hand, to the newly-created State hospital on the 1st of October, 1895. An appropriation of $25,000 is made for the lease or purchase of a dock and for the purchase of a steam ferry-boat. The medical officers of the present asylums are continued in office during the pleasure of the board of managers of the new State hospital, subject to the civil-service rules applicable to the other State hospitals.

FATAL TROLLEY ACCIDENTS IN BROOKLYN.—The continued serious loss of life by the trolley cars of Brooklyn has of late given rise to much indignation on the part of the public, and in the presentment of the February Grand Jury of that city, made on March 2d, considerable attention is given to the matter. "Investigation," it says, "has shown the imperative necessity of some prompt legislative action for the regulation of the speed of trolleys, with penalties severe enough to be absolutely deterrent to the management that leads to these shocking and harrowing accidents, and we earnestly request our representatives in Albany to do all in their power to secure the passage of laws that will give safety to our streets." As the accidents have almost all occurred in the older and more thickly populated parts of the city, the jury suggests that eight miles an hour should be the highest rate of speed permitted there, while in the newer and more sparsely settled the limit might be placed at ten or twelve miles.

ADDITIONAL PUBLIC SCHOOL ACCOMMODATION. — The Legislature recently passed a bill appropriating $5,000,000 for additional public school accommodation. This liberal provision will be ample not only to secure adequate accommodations for all the children who have been crowded out from the schools, but also to put all the school buildings now in use (with the exception of a few which will no doubt be abandoned on account of their radically defective character), in satisfactory sanitary condition. It is stated that since the opening of the schools in September last it has been found necessary to refuse admission to 12,316 pupils on account of the insufficient accommodation. Of the amount appropriated it is proposed to expend $3,000,000 in the erection of new buildings, and the remainder in enlarging and improving present buildings.

THE PUBLIC LIBRARY OF NEW YORK CITY. — An event of unusual importance during the past week has been the practical consolidation into one organization of the great Astor, Lenox and Tilden libraries. This will put at the disposal of the city a magnificent library, comprising at present more than 450,000 bound volumes and an immense number of rare and valuable pamphlets, and including property and endowments amounting to over $8,000,000. In general it may be said that the amounts which will go to make up the aggregate of the $8,000,000 to be administered by the board of managers of the consolidated library are composed of property and endowments as follows: about $2,000,000 from the Astor Library, about $4,000,000 from the Lenox Library, and $2,000,000 from the Tilden Trust. In addition to the last sum, the valuable private library of the late Samuel J. Tilden will be included. All these properties, under the scheme of consolidation, are to be thrown together in a common fund, passing absolutely out of the hands of the present directors of the separate institutions, and subject in future to the control of a consolidated board consisting of twenty-one members. The site of the new library has not yet been decided upon.

## Miscellany.

### DOUBT THROWN UPON THE "MISSING LINK."

IN a letter to *Science*, under date of February 14th, Harrison Allen ventures to doubt the validity of the "Pithecanthropus," the skeletal fragments of which were found in the early pleistocene strata of Java by Dr. Dubois, as was noted in the JOURNAL of February 21st. The skull of the "ape man" was acknowledged by Dr. Brinton, the reviewer of Dr. Dubois' memoir, to be like that of the famous Neanderthal man and the femora were described as "singularly human." Now on the evidence of the single molar tooth which has been preserved, and which, Allen thinks, conforms closely to the human type, he concludes that the "ape man" was in all probability a man, and not an ape in any sense of the word. Allen is supported in this opinion by a communication which appeared in *Nature*, January 29th, presumably from Richard Lydeker, who comes to the same conclusion on the evidence furnished by the skull, the femora and the tooth. This latest "missing link" must probably join its discredited predecessors, and the "ape man," if found at all, must be dug up from strata earlier than those of the early pleistocene of Java.

### BALDNESS AND INDIGESTION.

THE cause of baldness is a question which has a personal interest for many people in these days when the "new man" finds it almost as difficult to keep his hair as the "new woman" does to find a husband. The theory of the bald-headed man generally is that his exceptionally active brain has used up the blood-supply which should have nourished his scalp; but those whose crop of hair still stands untouched by the scythe of time unkindly hint that this explanation is of a piece with Falstaff's excuse that he had lost his voice by "singing of anthems." Then there is the theory of the hat, which we are told makes for sanitary unrighteousness in two ways — allowing no ventilation, and by its hard rim cutting off part of the blood-supply from the scalp. Again, there is seborrhea, which prepares the way for fungi that blight the hair. It would have been wonderful if that pathological scapegoat, indigestion, had not had this particular misdeed laid to its charge. We are not surprised, therefore, to read in an American contemporary that dyspepsia is the great cause of baldness. This is how the mischief is done: "Nature," we are assured, "is very careful to guard and protect and supply the vital organs with the proper amount of nutriment; but when she cannot command a sufficient quantity of blood-supply for all the organs, naturally she cuts off the supply of parts the least vital, like the hair and nails" — just as one of our "splendid paupers" discontinues his subscription to a hospital in view of the death duties. The hair, in fact, dies that the nobler parts may live up to a proper standard of physiological efficiency. The best way to escape baldness is therefore to be careful in our diet and above all to avoid irregularity in meals — a counsel of perfection which the busy man too often finds it impossible to follow. We are not prepared to deny that indigestion may have something to do with baldness, but the part it plays is probably altogether secondary. We

know of no evidence that baldheaded men are more dyspeptic than their neighbors, and women, who suffer much — chiefly through their own fault — from digestive troubles, are very seldom bald. The increasing prevalence of baldness might, with at least as much plausibility, be ascribed to the general betterment in our social condition that is taking place. The late Prince Consort (who himself lost his hair early) held that baldness is a sign of breeding; heredity, therefore, rather than indigestion would account for its frequency in the upper ranks of society. On the other hand, hairiness and anarchism often go together, as if the bomb-throwing brotherhood had determined to throw off even the mild tyranny of the barber with other forms of government. — *British Medical Journal.*

## A CASE OF SEXTUPLETS.

Vassali, in the *Gazetta Med. Ital. Lombardia*, gives an account of the birth of six children at one birth, which is said by von Herf[1] to be the first well-authenticated case on record. For some reason it has failed to attract general attention. The patient, a ii-para, thirty-six years of age, during the early months of her pregnancy, grew anemic, weak and complained of chilly feelings. Motion was not felt. In the fourth month of pregnancy the abdomen had grown as large as in ordinary pregnancy at full term, so that the woman daily expected confinement.

On the 115th day of pregnancy, while straining at stool, the membranes ruptured and a foot prolapsed, no pain having been felt before this incident. A fetus was delivered by a midwife. Vassali, who was called in the mean time, found the patient with an enormously-distended abdomen, within which were to be felt numerous small parts. No fetal heart was heard, nor were movements felt. As the cervix was but slightly dilated and no pains were to be felt, it was decided to wait.

On the next morning pains began with chills and flowing, the temperature rose to 38.7° C. with vomiting; and it was decided to terminate the pregnancy, as miscarriage was now inevitable. Accordingly the membranes were ruptured, a foot brought down and a second fetus delivered. A third bag of membranes presented, a third fetus was delivered; and so on till the fifth. This process lasted two hours, when fresh bleeding led Vassali to hasten the termination of what he thought was the third stage of labor, he naturally supposing that no further fetuses were to be expected. Traction on the umbilical cords was unsuccessful, and an attempt to remove the placenta by the hand in the uterus started so sharp a hemorrhage that Vassali, who was by this time completely exhausted, sent for assistance, not deeming it wise to attempt the removal of the placental mass.

He therefore kept his hand in the uterine cavity for four hours, until assistance arrived in the persons of three physicians from Lugano. Dr. Sulari with considerable difficulty removed the placenta, together with a sixth amniotic sac and fetus.

Convalescence was practically normal.

In the following year the woman gave birth to healthy twins, which were living at the time of this communication.

[1] Fortschritte der Medicin, October 4, 1894.

All the fetuses were born alive, and moved vigorously, the sexual organs were differentiated, four being males and two females. The large single placenta, bearing the six amniotic sacs, was unfortunately so lacerated that further investigation of it was useless. The specimen is preserved in the museum of the Obstetrical School at Milan.

## Correspondence.

### HUMAN EMBRYOS DESIRED.

Harvard Medical School,
Boston, March 2, 1895.

Mr. Editor: — May I take advantage of your kindness to appeal through your valuable columns, for assistance from practitioners in securing embryological material. I am desirous of greatly extending my researches on Human Embryology, and shall be very grateful for any material, and especially for normal embryos of three months *or less*. Of young human embryos the number which have hitherto been studied is still extremely small, and every specimen which can be secured for proper examination must be considered of great scientific value. I hope, therefore, that there will be very numerous responses to my appeal, especially since only by having very numerous embryos at command has it, in my experience, been found possible to obtain a few which are perfectly available for histological purposes. The difficulty is not that those who have furnished me with material were not sufficiently skilful in the methods of preservation, but on the contrary the difficulty comes from the rarity of the discharge of normal embryos while still fresh.

In regard to the treatment of embryonic material, it is, of course, best to receive it at the laboratory of the school whenever it can reach there really fresh in condition, for the resources here at command render a very careful preservation always feasible. When there is likely to be any delay, it is desirable to follow one of two methods: (1) If the membranes are intact, place the specimen *without opening the membranes* in a liberal quantity of strong alcohol, that is, full strength of 95 to 96 per cent. (2) If the embryo is exposed, the membranes being broken, place it in 60 per cent. alcohol.

Though young embryos are the ones most earnestly desired, older embryos are also valuable.

It need hardly be added that I shall be more than glad to pay any expenses incurred in preserving or forwarding embryos to me. I have the honor to remain

Yours respectfully,
Charles S. Minot, S.D.

### METEOROLOGICAL RECORD,

For the week ending February 23d, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer | Thermometer. | | | Relative humidity. | | | Direction of wind. | | Velocity of wind. | | Weather. | | Rainfall in inches. |

| Haverhill | 32,925 | 13 | 1 | 15.38 | 7.69 | — | 7.69 | — |
| Malden | 30,209 | 9 | 0 | 11.11 | 22.22 | — | 11.11 | — |
| Chelsea | 29,806 | 18 | 2 | — | 27.77 | — | — | — |
| Pitchburg | 29,283 | 7 | 3 | — | 14.28 | — | — | — |
| Newton | 28,837 | 16 | 4 | — | 56.25 | — | — | — |
| Gloucester | 27,293 | — | — | — | — | — | — | — |
| Taunton | 26,964 | 8 | 2 | — | — | — | — | — |
| Waltham | 22,038 | 9 | 2 | — | 22.22 | — | — | — |
| Quincy | 19,843 | 5 | 1 | — | — | — | — | — |
| Pittsfield | 18,802 | 5 | 1 | — | 20.00 | — | — | — |
| Everett | 16,585 | 5 | 4 | — | — | — | — | — |
| Northampton | 16,331 | 8 | 2 | — | 12.50 | — | — | — |
| Newburyport | 14,073 | 6 | 2 | — | 16.66 | — | — | — |
| Amesbury | 10,920 | 4 | 1 | — | — | — | — | — |

Deaths reported 2,556: under five years of age 778; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 330, acute lung diseases 602, consumption 295, diphtheria and croup 106, diarrheal diseases 26, typhoid fever 24, scarlet fever 23, whooping-cough 17, cerebro-spinal meningitis 13, measles 12, erysipelas 8, small-pox 1.

From scarlet fever New York 15, Boston 4, Brooklyn, Washington, Nashville and Somerville 2 each, Pittsburg, Charleston, Fall River, New Bedford, Haverhill and Woburn 1 each. From whooping-cough New York 10, Brooklyn 4, Boston, Providence and Worcester 1 each. From cerebro-spinal meningitis New York 4, Boston, Washington and Somerville 2 each, Lowell, Springfield and Lawrence 1 each. From measles New York 9, Lowell, Springfield and Lawrence 1 each. From erysipelas New York 5, Boston 2, Brooklyn 1. From small-pox Brooklyn 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530, for the week ending February 16th, the death-rate was 26.7. Deaths reported 5,430: acute diseases of the respiratory organs (London) 840, whooping-cough 93, measles 64, diphtheria 53, scarlet fever 36, fever 35, diarrhea 33, small-pox (London and Birmingham 1 each) 2.

The death-rates ranged from 14.5 in Croydon to 39.6 in Liverpool; Birmingham 25.7, Bradford 24.0, Cardiff 24.5, Huddersfield 20.4, Leeds 27.7, Leicester 21.3, London 29.3, Newcastle-on-Tyne 21.9, Nottingham 23.0, Portsmouth 20.9, Salford 25.8, Sunderland 20.4, West Ham 21.3.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 23, 1895, TO MARCH 1, 1895.

Leave of absence for six months, on account of sickness, is granted FIRST-LIEUT. FRANK T. MERIWETHER, assistant surgeon, U. S. A.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 2, 1895.

A. A. HOEHLING, medical director, detached from Naval Hospital, Chelsea, Mass., and granted three months' sick leave.

AMMEN FARENHOLT, assistant surgeon, detached from the Norfolk Navy Yard and ordered to the U. S. S. "Baltimore."

C. P. KINDLEBERGERM, assistant surgeon, detached from U. S. Receiving-ship "Vermont" and to the Norfolk Navy Yard.

ARTHUR W. DUNBAR, assistant surgeon, detached from the Naval Laboratory and Department of Instruction and to the U. S. Receiving-ship "Vermont."

J. B. PARKER, medical inspector, detached from duty in connection with the investigation of the Ford Theatre disaster and to the hospital and yard, Portsmouth, N. H.

D. MCMURTRIE, medical inspector, in addition to present duties to duty in connection with the investigation of the Ford Theatre disaster.

## OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE THIRTEEN DAYS ENDING FEBRUARY 28, 1895.

CARTER, H. R., surgeon. To assume temporary command of Cape Charles Quarantine during absence of Passed Assistant Surgeon T. B. PERRY. February 27, 1895.

KALLOCH, P. C., passed assistant surgeon. Directed to rejoin station, Cincinnati, O. February 21, 1895.

PERRY, T. B., passed assistant surgeon. To proceed to Brunswick, Ga., Quarantine, for temporary duty. February 27, 1895.

HOUGHTON, E. R., passed assistant surgeon. Granted leave of absence for two days. February 18, 1895. Leave of absence extended five days. February 22, 1895.

BLUE, RUPERT, assistant surgeon. To proceed to San Francisco, Cal., for duty. February 23, 1895.

## HARVARD MEDICAL SCHOOL.

EVENING LECTURES.

The next lecture will be given on Thursday evening, March 21st, at 8 o'clock, by Asst. Prof. W. T. Porter. Subject, "The Physiology of the Cortex of the Brain." Physicians are cordially invited.

## SOCIETY NOTICES.

AMERICAN MEDICAL PUBLISHERS' ASSOCIATION. — The annual meeting will be held in Baltimore, on May 6th, convening in the parlors of the Eutaw House, at 9.30 A. M.

CHARLES WOOD FASSETT, *Secretary*.

## RECENT DEATHS.

FRANK L. DUBOIS, medical inspector, United States Navy, died of apoplexy, February 24th, at Portsmouth, N. H. He had been thirty-three years in the service.

DR. GEORGE OCTAVE DUJARDIN-BEAUMETZ died in Paris, February 16th, aged sixty-one years. He was made a commander in the Legion of Honor in 1894. He was editor-in-chief of the *Bulletin de Thérapeutique* and the author of many suggestive works on subjects in clinical medicine, therapeutics and hygiene. He was visiting physician at the Cochin Hospital for many years.

JOHN WHITAKER HULKE, President of the Royal College of Surgeons of England and senior surgeon to the Middlesex Hospital, died in London, on February 19th, from broncho-pneumonia, following influenza. He was sixty-five years of age. He was eminent not only as a general and ophthalmic surgeon, but as a geologist and palæontologist. He was president of the Clinical Society of London, at a meeting of which he presided on the evening of February 8th. He was to have delivered the Hunterian oration on "John Hunter the Biologist," on February 14th, but was prevented by the illness which resulted in his death on the 19th.

## SUDDEN DEATH BY THE RUPTURE OF THORACIC ANEURISMS PREVIOUSLY UNRECOGNIZED.[1]

BY F. W. DRAPER, M.D.,
*Medico-Legal Pathologist, Boston City Hospital.*

The autopsy-room of a hospital is specifically dedicated to the study of morbid anatomy. Its air is heavy with the effluvia of disease, decay and death. Its ministering spirits, with erudite touch and penetrating vision, search out the secrets of nature. Infection, inflammation and degeneration render here their final account. The pathologist supplies the closing chapter in the natural history of diseases whose earlier incidents are written in the clinical records relating to the living patient. The first and the last observations upon the human subject, in connection with his fatal illness, sometimes fail to connect harmoniously, and the ward bed and the marble slab sometimes present details which do not blend. Nevertheless, the aid which clinical medicine derives from the anatomical amphitheatre of the hospital is too obvious to need elucidation. The aphorism of Dr. Holmes that, while pathological anatomy teaches a great deal, "it is, after all, like inspecting what is left of the fireworks on the morning of the fifth of July," is less true today then when he wrote it. Histology and bacteriology now lend their effective aid to the grosser methods of observation, and pathology co-operates heartily with clinical medicine in the advancement of medical science.

But the autopsy-room of the City Hospital of Boston has not exhausted its usefulness, great as that service is, by discovering and recording the anatomical appearances which the hospital patients bring to the dead-house after a period of observation in the wards. Through the courtesy of the trustees, and with the indulgent and cordial assent of the pathological department, autopsies are made here upon the bodies of such victims of crime or such subjects of sudden and suspicious deaths in the southerly portion of Suffolk County as require an official medical examination. It thus happens that many interesting medico legal problems are presented here for solution. The privileges bestowed upon the medical examiner by the hospital place him under continued obligation. It is in recognition of this debt and of the very great help in the medical examiner's work which it implies that he accepts the invitation to contribute to these pages.

In fulfilment of this design, I have selected from notes of autopsies performed by me at the hospital a series of cases of thoracic aneurism. These cases are all instances of sudden death. Their subjects have this in common, that the disease of the aorta which ended life so suddenly had not been suspected or recognized or been made the occasion of medical observation or treatment. In this respect they illustrate a rule about which all writers are agreed, that a large number of aneurisms declare no sign of their existence, and that they are revealed by the post-mortem examination only. They show how imperceptible and with how little injury to health may be the growth of even a large aneurismal tumor. Finally, they are examples of the usefulness of autopsies in determining accurately the causes of tragically sudden death, and in taking the obscurity out of cases which are too often dismissed with a convenient expression like "heart disease" or the more objectionable but equally convenient phrase, "heart failure."

[1] This paper will appear in the Boston City Hospital Reports, Sixth Series.

Case I. Josephine S., aged thirty-seven, a hard-working charwoman, entirely free from disabling disease though a moderate user of alcoholic drinks, was found dead, lying in a natural attitude on the outside of her bed, with her outer clothing removed. She was last seen alive twenty-three hours previously. Her body when discovered was cold, and rigor mortis was fully devoloped. Her acquaintances supposed her to be a healthy woman.

*Autopsy.* — The body was spare but not emaciated. The countenance presented no suggestion of a painful death. The surface was pale.

When the sternum was lifted the left pleural cavity was found filled to its fullest capacity with yellow serum and dark-red, firm blood-clot, the whole mass measuring two quarts. This blood had escaped from a rupture in the inferior wall of an aneurism of the aortic arch. The aneurismal tumor projected posteriorly opposite the fourth, fifth and sixth dorsal vertebræ, and had eroded the vertebral bodies and intervertebral cartilages in this region to the depth of a quarter of an inch at the deepest, leaving the general surface roughened and irregular. The aneurismal sac was ovoid in shape, and measured four inches long, three inches wide, and one inch and a half thick. Within it were masses of firm coagulum, with dry, shreddy layers of fibrin.

The rupture was at the lowest part of the sac. The opening was valvular, from above downward. Externally it appeared as a rent in the aneurismal wall just below the root of the left lung, the lesion being irregularly crescentic, with the concavity downward, and with an opening at its uppermost part admitting a large probe.

The heart was normal. The left lung was compressed, dry and pale; the right lung was of normal volume, and moderately reddened. The other organs showed nothing noteworthy.

Case II. John J., aged forty-three, intemperate and shiftless, had not been heard to complain of any ailment until the morning of the day of his death. At this time he procured from a druggist a "plaster for his chest." About three hours later he was seen on the street, looking so distressed that an acquaintance remarked upon his appearance, and J. replied, "I *am* sick." Presently he went into a store and sat down; he quickly became stiffened in a convulsion, was rigid and unconscious, breathed stertorously, gasped a few times and died, the whole transaction occupying but a few minutes.

*Autopsy.* — The surface of the body was very pale; there were scarcely any lividities of the skin. The mucous surfaces were blanched. Cadaveric rigidity was pronounced.

The heart was healthy and empty. The lungs were normal, though rather anemic.

In the abdominal cavity were sixty-six fluid-ounces of mingled fluid blood and blood-clot. The source and course of this hemorrhage were found to be as follows: At the junction of the transverse and descending portions of the aortic arch there was a projecting aneurism, with thin walls, the tumor being the size of an English walnut. This outgrowing sac had ruptured at its outer

part, and the escaping blood had dissected its way inside the sheath of the aorta, leaving a blood-stained track in the posterior mediastinum. It had then torn through the diaphragm between the aorta and the esophagus. It had then turned to the right, across the cardiac end of the stomach posteriorly, and here, tearing away the peritoneum of the stomach over a surface two inches by three inches, it had broken through and discharged into the general peritoneal cavity.

All the organs of the abdomen were structually healthy. The brain was pale and wet.

CASE III. Winifred M., aged sixty-five, a homeless wanderer, depending on street alms and the poor hospitality of her acquaintances to keep her from starvation, was not known to be the subject of any disease, although she had been heard once to make an allusion to her "heart" as the seat of some indefinite disorder. On the day before her death she was on the street from morning till night, and returned to her temporary lodging in her usual health. Her bed was prepared for her on the floor, and she went to sleep at ten o'clock. In the night she shifted her bed from the corner of the room to the middle; and here at 7 A. M., she was found dead without any indication of distress in her attitude or countenance.

*Autopsy.* — The body was emaciated. The surface was pale, with some cadaveric lividities upon the dependent parts.

When the sternum was removed, the pericardium was observed to be distended, bulging outward, and freely exposed; it contained ten fluid-ounces of blood, fluid and clotted. The heart was moderately and symmetrically enlarged; its muscle was readily crushed by finger pressure. The aortic valves were moderately thickened at their free border, but were competent. The mitral valve was normal.

The aorta, beginning at a point near its origin, was dilated; the enlargement was rather greater on the upper or convex border, was fusiform in shape, without sacculation, and in size and contour resembled a lemon. The wall of the dilated artery was thinned to an appreciable degree; and the intima, not only of the arch, but of the entire thoracic portion as well, showed large patches of atheroma, some of them with calcareous plates.

Immediately to the right of the innominate artery, on the upper curve of the transverse part of the arch, there was a rent in the intima of the aortic wall, transverse in direction, and one inch long; the edges of the rupture were irregularly indented, but the general direction was linear and straight. The situation of this internal rent was above the line of the pericardial attachment. But the blood, instead of forcing its way directly out at this point, had dissected a passage backwards and downwards, along beneath the outer coat of the artery, and had found its entrance into the pericardial enclosure, through a longitudinal rent an inch and a half long, and two inches below its rent of exit through the inner coat of the aorta. The tissues between the two ruptures were infiltrated with blood.

Both pleural cavities were obliterated by old pleuritic adhesions. Both lungs were engorged. There was no blood in the bronchi.

There was no sign of disease about the abdominal or pelvic organs. The brain was normal in appearance.

CASE IV. Joseph F., aged seventy-five, was alive and well at 6.30 A. M., when his room-mate left him at home. He had been out of doors through the previous day, and was not known to have any ailment. At 1 P. M. he was found dead on the floor of his bedroom. He was in a kneeling posture, with his forehead resting on the floor in front of him. His trousers were down about his thighs.

*Autopsy.* — The body was spare. Rigor mortis was fully developed. The face was livid.

The pericardium was distended and bulging, showing a dull purple color through its wall. It contained twelve and a half fluid-ounces of blood, fluid and clotted, the clot being soft and of a dark color.

The heart was normal in appearance; its valves were all competent and in healthy condition.

The aorta was dilated; its intima was thickened and roughened from the semilunar valves to the iliac bifurcation, the result of atheromatous degeneration.

Just above the anterior coronary orifice, in the ascending portion of the aortic arch, there was an aneurismal sac projecting outward and to the right, and having a cavity of about the size and shape of a large olive. At the outer aspect of this small sac was a crescentic, valve-like rent, extending downward into the pericardium. The external lesion in the outer coat of the vessel was curvilinear, three-quarters of an inch long. The orifice through which the blood escaped through the intima was irregularly rounded and of the about the size of a pea.

The lungs were injected. The spleen was softened almost to a condition of diffluence; it was small, dark red, and adherent to the adjacent tissues by the products of former inflammation. The stomach and intestines were normal. The liver showed the appearances of fatty infiltration. The kidneys represented chronic interstitial inflammation. The brain was unnaturally moist.

CASE V. Leodegar M. L., aged fifty-one, was found dead in his room in a hotel, lying back against some pillows on a lounge, one foot on the lounge and the other hanging off its edge. An hour and a half previously he had walked up the three flights of stairs leading to his room, and seemed in his usual good health and spirits when he entered the hotel office.

He was the subject of a lateral curvature of the spine, and to his acquaintances this appeared to be his only disability. It was ascertained from one his intimate friends, however, that for many months he had had pain in his shoulders and in the right sub-clavicular region, to such a degree that he had talked of sudden death as a possible termination of his trouble. The last evening of his life he had seen a well-known and experienced physician who gave him some advice of a general nature, but did not entertain the idea of any serious organic disease.

*Autopsy.* — The body was emaciated. The countenance indicated distress. There was a marked lateral curvature of the spine in the dorsal region, which gave also a "pigeon-breasted" deformity to the sternal region.

When the sternum was removed, the pericardium was observed to be prominent, distended and elastic, showing dark contents through its translucent wall. It contained sixteen fluid-ounces of blood, fluid and clotted. The source of this hemorrhage was found to be a minute rupture in the wall of an aneurism of the ascending and transverse portions of the aortic arch. This portion of the artery was enlarged to about twice its normal size; its intima was rough and thick. From

the outer and upper part of the ascending section a secondary projection was found, the result probably of a former rupture of the aortic wall. The wall of this smaller sac was relatively thin, and was lined with loose, rather dry clot. At its upper border, as close as possible to the pericardial line, was a minute orifice, hardly admitting the head of a small probe. The size of the sac was that of a large apricot.

The heart was firmly contracted and empty; its structure was normal. There was no effusion of blood outside the pericardium. The lungs were injected; in other respects they were normal. The spleen and kidneys were reddened. The other organs were healthy in appearance.

Case VI. John H. H., aged fifty-one, ran to catch a train which was about to start. He entered a car and took his seat. Presently he was observed to be ejecting blood copiously from his mouth; his death quickly followed. It was learned from his kindred that he had been ailing many months with some obscure symptoms which represented "heart disease" to him; but he had not been incapacitated for the performance of his daily duties. He himself had anticipated sudden death.

*Autopsy.*— The body was sparely nourished. The surface was pale. Post-mortem rigidity was pronounced. Dried blood was in the nostrils, on the mustache and beard, and on the lips and teeth.

On raising the left lung, a firm adhesion was found posteriorly, near the apex, tying the lung to the spinal column and the adjacent ribs, over a surface two inches in diameter. When the heart, lungs, esophagus, and aorta were removed together, this area of adhesion was found to be a portion of the wall of an aneurism of the thoracic aorta, involving the lower section of the descending portion of the arch as well. The aneurism consisted almost wholly of the dilated arterial walls, much thinned; there was no deposit of fibrinous layers within it. The lining surface was rough from atheroma, with projecting calcareous plates. The part next to the spine, where the adhesion was found, had eroded the bodies of the vertebræ to a slight extent. Just in front of this eroded space, the aneurism had ruptured in a forward and upward direction into the upper lobe of the left lung. At the point of rupture, the wall was thinner than elsewhere. The rent was irregular and somewhat stellate in shape, and admitted the tip of the finger. The size of the aneurismal cavity was about that of an orange.

The entire arch of the aorta was considerably dilated, and its intima was roughened and thickened. The aorta below the aneurism also showed atheromatous changes, without dilatation.

The heart showed no change whatever from the normal condition, in size, thickness of its walls, color of its muscle, or state of its valves. Its cavities were empty, and its left ventricle was contracted.

The left lung at the point opposite the aneurismal rupture showed an excavation half an inch deep and of irregular periphery; all around this the tissues were infiltrated with blood, giving an engorged appearance to the entire upper lobe, and, to some extent, the upper part of the lower lobe also. There was no blood in either pleural cavity. The right lung was somewhat reddened. The trachea and bronchi contained blood, and there were about four fluid-ounces of clotted blood in the stomach.

The other organs showed nothing noteworthy.

Case VII. An unknown woman about sixty years old, presenting the aspect of a homeless street-beggar, was seen to stagger across Atlantic Avenue and to drop helplessly upon some store steps. She was bleeding from the mouth. She was insensible when the bystanders reached her, and presently she died. The front of her dress was blood-stained, but the evidences of very profuse hemorrhage were wanting. The body was not identified, and therefore all knowledge of her health previous to her attack on the street is lacking.

*Autopsy.*—The following appearances were the only ones of immediate interest: The upper portion of the thoracic aorta, just below the arch, presented an aneurismal dilatation of the size of a large orange; it was located opposite the bifurcation of the bronchi. Portions of the wall were very thin, while other parts were much reinforced by layers of fibrin. The aneurism had ruptured into the bronchi. There was no blood in the pleural cavities. The lungs were engorged, and the bronchi and trachea contained frothy blood. The heart was enlarged, the hypertrophy being chiefly on the left side. The aortic valves were thickened, and behind them were small calcareous plates of great density. The aorta was dilated just above the valves, and at one point in the ascending portion the walls had yielded, forming a depression one inch in diameter and a quarter of an inch deep. The intima of the aorta throughout its extent was thick and rough.

Case VIII. Michael F., aged seventy-seven, was seen to topple over as he was in the act of crossing Park Square at 10 o'clock A. M. Medical attendance was immediate, and the man was placed in an ambulance and transferred quickly to the City Hospital. On his arrival he was in a state of profound collapse. He gave his name and address, but no other facts. He died at 10.45 A. M., three-quarters of an hour after the seizure. His family stated later that they had had no knowledge of any disability of which he was the subject.

*Autopsy.*— The body was spare, and its surface was pale and exsanguine. The pericardium, prominent and bulging when first exposed, was found to contain a pint and a half of fluid blood and soft clots. The heart was moderately enlarged, and its left ventricle showed a thickened wall; its valves were normal.

The arch of the aorta was much dilated, its lumen being expanded into a cavity of the size of a large lemon. In the descending portion of the arch, just behind the pulmonary artery, there was a transverse rent in the intima, two and a half inches long, linear, straight, but not penetrating into the pericardium; the most careful exploration failed to discover any communicating opening, and the conclusion was that the leakage seemed to be by filtration through the outer layer of the aorta's wall. The inner coat of the aorta was thick and rough, and the lumen of the artery below the arch was narrow and irregular. The tissues in the posterior mediastinum and in the posterior parts of both lungs were fully infiltrated with blood; the lungs elsewhere were edematous. About a pint of thin, bloody serum was found in the pleural cavities.

The spleen, pancreas, stomach, and intestines were normal. The liver represented passive congestion. The kidneys were typical specimens of chronic interstitial inflammation.

CASE IX. Chipman H. S., aged thirty-seven, was admitted to the City Hospital about 10 o'clock P. M., January 20th, at the request of a physician who stated that the man was suffering from paraplegia, in some way connected with two doses of a poisonous drug prescribed by an irregular practitioner. It appeared from S.'s story that he had not suffered any disability until the forenoon of that day; at this time his "legs gave out" and he sank to the floor of his room. He said he had great pain in his back, not localized, but general. There was also an account of vomiting and of the passage of bloody matter in his dejections, and this lent some aid to the theory of poisoning.

At the hospital a loud souffle was heard over the heart. The man was restless, very thirsty, and disinclined to talk. Toward morning, January 21st, he sank into a stupor and had some equivocal convulsive movements. He gradually failed, and died at 12.05 P. M., that day. The hospital diagnosis was not conclusive, but cerebral hemorrhage seemed the probable condition.

*Autopsy.* — The body was well nourished and of good muscular development. Cadaveric lividities were more than ordinarily pronounced on the lateral and dependent parts.

The heart was hypertrophied without dilatation. Its valves were all in normal conditiou. The myocardium was pale but firm. The aortic arch was dilated moderately and displayed old endarteritis. The aorta below the arch and to within five inches of the diaphragm was normal. At this point, just above the diaphragm, there was an aneurism of the size and shape of a large kidney. Its anterior wall was adherent to the posterior surface of the lower lobe of the left lung. Its posterior wall was the exposed and eroded bodies of the eighth, ninth and tenth dorsal vertebræ; the necrosis of these bones had gone so far as to leave upon the front and left side deep excavations into which the forefinger could easily be laid, leaving a thin shell of denser bone at the upper and lower margins, with the intervening cartilages in place. Around this bony destruction the aneurism was firmly attached to the bone at either side. The contents of the sac consisted of laminated and rather dry, easily broken blood-clots, brownish-red in color, through which ran a tortuous blood canal of the size of the finger.

The lungs, spleen, stomach, intestines and liver were healthy. The kidneys were injected. The brain was of normal appearance.

The spinal cord was taken out from behind. The vessels of the dura were injected throughout the dorsal region. The body of the tenth dorsal vertebra, in front of the dura, was carious and dark-red. The ninth vertebra showed less change. There was a marked excess in the spinal fluid, fully distending the cavity of the dura. The vessels of the pia were fully injected, especially along the anterior surface of the cord. In the anterior and left lateral columns of the cord, near the affected vertebræ, there was a marked degree of reddening, in contrast with the color above and below; but the consistence of the cord was normally firm.

CASE X. Patrick J. S., aged thirty, a tailor by trade, had been ailing many months with an obscure pain in his right side; and, also, at times, with what he had called "neuralgia of the heart." He had received medical treatment for "liver complaint." He had kept at his work, without interruption, up to the hour of his death. The first symptoms of his approaching end were pallor and great dyspnea. He entered a liquor store, where he was known, and sat down "panting for breath." A carriage was called, and the man was placed in it and started for the City Hospital. He died on the way.

*Autopsy.* — The body was lean. There was rather more than the usual degree of cadaveric lividity.

The left pleural cavity contained ten fluid-ounces of thin, red fluid. Both lungs were, in general, gray in color, and were thoroughly edematous and sodden. The right lower lobe and left upper lobe were injected more than other parts; but the reddening was very moderate in degree. The pericardium contained five fluid-ounces of straw-colored serum. Both ventricles were firmly contracted; their walls were not thickened. The several valves were normal.

An aneurism projected from the anterior wall of the aorta, immediately above the semilunar valves. Its size was that of a small orange. Its wall was translucent at its most projecting part; elsewhere it was lined with friable coagula, or masses of fibrin, and was opaque and thickened. The orifice of entrance to the sac, seen from within the aorta, was one inch above the right semilunar valve, and appeared as a round aperture through the wall of the vessel; the opening admitted the tip of the forefinger.

The aneurism was so located that it overlay and nearly obliterated the lumen of the pulmonary artery just above its origin at the heart. The aortic arch was moderately dilated, and its intima was thick and uneven.

The other organs of the body displayed nothing noteworthy.

---

In addition to the features which the foregoing cases have in common (the suddenness of their termination and the fact that the development of serious aortic disease had never been discovered or treated), these deaths suggest some points of special interest, among which the following may be deemed worthy of mention:

(1) The rupture of an aneurism of the aorta, although it sometimes has physical exertion as its exciting cause (Cases V and VI), does not of necessity require such a cause (Cases I, III, VIII).

(2) The pericardium, more often than other cavities, receives the escaping blood; and, in these cases, it is not the amount of the hemorrhage which kills, but the inhibition of the heart's action, by compression of the cardiac walls, in a sac filled to distension with blood (Cases III, IV, V and VIII).

(3) Deaths by aneurismal rupture, although deserving the description "sudden" are not instantaneous; an appreciable interval (Case VI), and, sometimes, a very considerable period, elapses between the attack and its termination (Cases VII and VIII).

(4) A death by aneurismal rupture is not generally a painful one (Cases I, III); although it may leave evidences that it is so in some cases (Cases IV and V).

(5) The escaping blood in an aneurismal rupture does not always follow the line of least resistance (Case II); and, sometimes, it makes a devious dissection to reach an outlet (Cases III, IV).

(6) Its small size and fusiform shape do not give

an aneurism immunity from sudden rupture (Cases II, III, IV, VIII).

(7) An aortic aneurism is not necessarily an affair of advanced life (Cases I, II, V and VI).

## THE ANTITOXIN TREATMENT FOR DIPHTHERIA.[1]

### A CLINICAL REPORT.

BY CHARLES F. WITHINGTON, M.D.,
*Assistant Visiting Physician, Boston City Hospital.*

THE object of the present paper is to report the results of the treatment of diphtheria by antitoxin in a series of cases in my recent service in the contagious wards of the City Hospital. This service comprised the two months of December and January. Through the enterprise and liberality of the trustees a supply of antitoxin was secured about December 12th, and the first injection was made on that date. The first twenty injections were made with the solution prepared under the direction of Behring and Scherer, and the remainder were with the product of Dr. Gibier, from the Pasteur Institute in New York. Most of the former series were made with the "No. 1" strength, of which ten cubic centimetres, the dose usually given, contains 600 immunization units. In a few cases the No. 2, representing 1,000, and the No. 3, representing 1,500 antitoxin normals, were used. The Gibier product was furnished in two strengths, marked 1–50,000 and 1–80,000, the latter of course the stronger, as one part was supposed to immunize an animal of 80,000 times its weight against what would be to it a fatal dose of diphtheria toxine. Dr. J. L. Morse, who made some tests of this material found that a specimen marked 1–80,000 actually immunized a guinea-pig of 11,500 times its weight against ten times its fatal dose of toxine.

The treatment, other than antitoxin, employed in the cases to be reported, was frequent feeding, alcohol, iron and cardiac stimulants as required. Locally, irrigation was practised with normal salt solution, or diluted Dobell's solution, whenever it could be done without provoking great resistance from the patient. When violent resistance was encountered which seemed to exhaust the patient's strength, irrigation was omitted.

Before passing to the consideration of the antitoxin cases it is worth while to say a word regarding the cases which were treated during the same interval without antitoxin. This latter group, rejecting all which did not show the Klebs-Löffler bacillus, comprised 40 cases. The reasons why antitoxin was not employed in these cases were as follows:

In nine cases, lack of serum; that is, in nine cases which were suitable for treatment the material was not at hand. Of these, three died.

In six cases, lateness in the disease. In these the patients had been ill five days or more when they came under treatment, and in the scarcity of the material it seemed wise to withhold it in favor of more promising cases. It is to be noted that it was the lateness and not the gravity of the disease which governed this selection. Three of these patients died, and three recovered.

In five patients antitoxin was withheld because they entered moribund. All these died within two days of entrance.

In two cases, antitoxin was withheld because of a negative report from the bacteriologist on the first examination, although the second examination showed the diphtheria bacillus. Of these two cases one died. A corollary of this is that in cases clinically diphtheria it is not well to wait for a bacteriological verdict before using the remedy, and so to lose valuable time.

In 18 cases the remedy was withheld because of the mildness of the disease and the probability that the cases would recover without antitoxin. They all did recover.

On the whole it may be said that the group of 40 cases represented rather less than the average gravity of the disease. The deaths were 12, or 30 per cent., and the recoveries 28, or 70 per cent. Three of the deaths were intubation cases, and no intubation in this group recovered. It may be said in passing that there were five other non-antitoxin cases which had laryngeal membrane and failed to show the diphtheria organism, of which two recovered without operation, two with operation, and one died after operation.

The average duration of the residence in the hospital of the 28 non-antitoxin diphtherias which were discharged well, was fourteen days.

Turning now to the group of antitoxin cases, I have to report 80 cases of diphtheria treated by this remedy between the dates above mentioned. As a matter of fact, 91 cases which would clinically be classed as diphtheritic received injections; but I have excluded from the list all who failed to present the bacteriological evidence of the disease. In reality, I believe some of them to have been, notwithstanding the negative report of the bacteriologist, true diphtheria; and their inclusion would of course raise the percentage of recoveries of the treatment. For example, among the 11 cases were two of membranous laryngitis, intubation and recovery, and two children with membranous throats, one of them septic, who had brothers or sisters in the hospital at the same time, with undoubted diphtheria, a fact strongly presumptive of the diphtheritic nature of the membrane in the other children.[2] In order, however, to disarm criticism, I exclude all these cases; and we have left 80 patients clinically and bateriologically suffering from diphtheria. The cases represented rather more than average severity, especially during the earlier part of the series. In view of the scarcity and expensiveness of the material, such cases only were selected for treatment as were of sufficient gravity to make it reasonably likely that they would prove to show the diphtheria organism.

Of these 80 patients, 13 died, a mortality of 16 per cent. A study of these fatal cases may be of interest and profit, and I will therefore briefly describe them. As to the first two, there is considerable doubt as to whether they should be considered deaths due to diphtheria, though I have included them in the list.

CASE I. G. B., male, age six. Entered December 9th. Injected December 12th, on the seventh day of his illness. Membrane disappeared in two days, but returned. Reinjected December 18th. Contracted scarlet fever December 21st, from which he died Jan-

[1] Read before the Boston Society for Medical Improvement, February 18, 1895.

[2] Of the occasional failure of bacteriological evidence of diphtheria, I would cite an instance in one child (Mullaney), who had membrane on both tonsils and palatine arch, and a nasal discharge. Two cultures from the throat showed pure staphylococcus aureus; two from the nose also failed to show the diphtheria organism; and, finally, a fifth culture, twelve days after entrance, showed for the first time the Klebs-Löffler bacillus, and that in the nose only. This patient is living at the present writing, twenty-two days after his first injection, but is not yet well. He is, however, the only one of the non-fatal cases which is not convalescent.

uary 5th, septic, but two days after Klebs-Löffler bacilli had disappeared from his throat, twenty-four days after his first injection, and thirty-one days after the onset of his diphtheria.

CASE II. A. H., boy, age four years. Entered January 21st. Period of disease unknown. Injected January 22d; Gibier solution, 1–50,000, 20 c. c. Klebs-Löffler bacilli; then disappeared in four days. Then irregular, rising temperature; scarlet fever; broncho-pneumonia. Died February 7th, seventeen days after entrance.

CASE III. N., age twelve. Admitted January 24th. Membrane tonsils, pharynx, nose. Enlarged glands, intense sepsis. Injected January 25th, second day of illness; 25 c. c. Gibier solution, 1–50,000. Second injection January 27th, Gibier solution 10 c. c. Hemorrhages, nose and mouth. Membrane much diminished on fourth day, but what is left not well demarcated. Died January 30th. Klebs-Löffler still present.

CASE IV. A. B., female, age three. Sick on or before December 8th. Injected December 12th. Behring No. 1, 10 c. c. Died in five hours. Profound sepsis. Membrane tonsils, pharynx and nose.

CASE V. A. M., female, age eight. Taken sick December 6th. Injected December 13th. Behring No 1, 10 c. c. Membrane tonsils and palate. Reinjected Behring No. 1, 5 c. c., December 21st. Klebs-Löffler and streptococci. Lived twelve days after first injection. Membrane nearly disappeared, later returned. Died of heart-failure.

CASE VI. D. M., female, age three. Admitted December 19th. Duration unknown. Intubed December 20th, and not injected because thought to be moribund. Being still alive December 21st, injected as forlorn hope, *very late* (unknown how late) Behring No. 2, 8 c. c. Same day tube removed; broncho-pneumonia. Died December 22d.

CASE VII. A. J., a female, age ten months. Nursing child, both parents in hospital with diphtheria. Injected December 29th, five days after onset. Sepsis profound. Membrane tonsils, pharynx and nose. Vomited everything. Died December 31st.

CASE VIII. C. O'D., male, age two. Sick three days. Entered December 31st. Intubed at 11 A. M. Gibier, 1–50,000, 6 c. c. Died 11 P. M., same day.

CASE IX. V. E., male, ten months. Bottle fed. Sick eight days. Injected Gibier, 1–80,000, 7 c. c., January 3d, and 6 c. c., January 5th. Membrane much diminished after second injection. Later returned; vomited everything. Died January 11th.

CASE X. A. N., male, twenty months. Mixed infection of Klebs-Löffler and streptococci. Sick three days. Injected Gibier, 1–80,000, 7 c. c., January 3d, and 6 c. c., January 4th. No improvement whatever. Died January 6th.

CASE XI. J. C., male, age fifty-five. Had been "spitting up pus" three or four weeks; cause of this unknown. Klebs-Löffler and streptococci. Injected, December 28th, 14 c. c. Gibier, three days after onset, and December 30th 8 c. c. Sepsis, hemorrhages, cyanosis, delirium, obstruction, tracheotomy. Death January 1st. No improvement here. Extension downward. See autopsy, *infra*.

CASE XII. J. F., male, age five. Sick four days. January 17th, injected 20 c. c. Gibier, 1–80,000. January 18th, reinjected 16 c. c. Gibier, 1–50,000. January 19th died. Profound sepsis, hemorrhages. Membrane in throat, palate and nose. See autopsy, *infra*.

CASE XIII. H. S., age three. Entered January 17th, and was intubed at once. Injected, January 18th, Gibier, 1–50,000, 16½ c. c., eight days after onset. Entered partly unconscious. Pneumonia same day. Died day of injection.

It will be seen that of these 13 cases four died within the first twenty-four hours after the first injection, and two others died within the second twenty-four hours. The average time which elapsed in these fatal cases between the onset of the disease and the injection was almost exactly five days, a period so long as to seriously invalidate the efficacy of the serum treatment. On the other hand, the treatment was given early in two or three of the cases, and the conditions seemed those which ought to have led to better results than those attained.

The extent of the invasion in some of the fatal cases is illustrated in two autopsies.

CASE XII. Autopsy twelve hours after death showed "diphtheritic inflammation of the tonsils with ulceration and necrosis, hemorrhagic broncho-pneumonia and purulent bronchitis of both lungs, and discrete patches of fibrinous pleuritis, general acute lymphatic hyperplasia, acute splenic tumor, cloudy swelling of kidneys, liver and heart muscle. . . . Bacteriologically, the tonsils showed many colonies of Klebs-Löffler and short, thick bacilli. In the lung were very many colonies of typical Klebs-Löffler and a few larger colonies of streptococcus pyogenes from broncho-pneumonia. The heart's blood showed a few colonies of typical streptococci, and the kidney a few typical Klebs-Löffler and streptococci."

CASE XI. Autopsy, adult. "Anatomical diagnosis — tracheotomy wound: diphtheria affecting uvula, soft palate, left tonsil, larynx, trachea and bronchi; emphysema, broncho-pneumonia. Bacteriologically: Lung, broncho-pneumonia, moderate number of colonies of colon bacillus, a few of diphtheria. Larynx, many colonies of Klebs-Löffler. Brain, a few colonies of colon bacillus. Heart's blood, sterile. Liver, sterile. Kidneys, a few colon bacilli."

Among the fatal cases were three of intubation and one of tracheotomy. Of the intubations, in one the injection preceded the operation, and in two the intubation preceded the injection. The tracheotomy was performed three days after the first injection, and was a fruitless attempt to ward off an asphyxia due to pulmonary extension and sepsis.

In one case of intubation where the injection preceded the operation, recovery took place. The tube was left in the larynx only three days.

Combining now, the 80 cases of diphtheria treated by antitoxin with the 40 treated otherwise, we have a total occurring in the period covered, of 120 cases with 25 deaths, a mortality of a little less than 21 per cent. The average hospital mortality from diphtheria is from 45 to 50 per cent. For the corresponding period in the previous year, December 12, 1892, to January 20, 1894, there were 84 cases of diphtheria with 44 deaths, a mortality of 52 per cent.

We have thus, I think it must be admitted, evidence of a very substantial reduction in the death-rate of diphtheria under the antitoxin treatment. But the mathematical expression of the fact is not to my mind the most striking one. The general appearance of the

patients, the look of the ward is different from what it formerly was. It is a common thing to see a child within 24 hours after an injection, sitting up in its crib and playing with its toys. In cases where I have wished as a safeguard to the heart, to keep the child recumbent, it was very difficult to do so, the buoyancy of improving health asserting itself in this way unless a nurse is constantly at hand to restrain the child from sitting up. There are a less number of children than formerly lying about in that dull, comatose condition of profound, advancing sepsis, and the aspect of the ward is more like that of a convalescent hospital than of a lazaretto. There is less steam needed for the relief of choking patients. The proportion of operative cases is, I think, less. Five of the cases, as I have said, came to operation, and the mortality of them was large, 80 per cent.; but four others who entered croupy, with labored breathing and retraction, and who seemed destined to an early operation, recovered without that necessity.

The duration of the residence in the hospital of the antitoxin-treated cases, furnishes an interesting comparison with that in the cases not so treated. As I have already said, the latter group showed an average hospital residence of 14 days for the cases which recovered. In the antitoxin group, the average hospital residence of 58 cases which recovered and were uncomplicated with other diseases (for nine children developed either scarlet fever, measles, chicken pox or some other affection which increased their hospital residence) was eleven days. Hence arises the deduction, interesting from the financial point of view, that the hospital saved in this treatment an average of three days' board for each patient who recovered, which was enough to a little more than pay for the antitoxin used. Moreover, it may be mentioned in this connection that the omission in these cases of other treatment often pursued made a still further saving, the one item of peroxide of hydrogen (none of which was used in any of the cases) having cost the hospital about $550 the previous year. Thus it is pleasant to see how a liberal policy works even a financial saving!

The patients were all retained in the ward until the disappearance of all visible membrane and two negative reports from the bacteriologist as to the existence of the diphtheria bacilli. These bacteriological examinations were, so far as possible, made daily and the record shows the date at which the membrane was gone, and the first permanent disappearance of the bacilli. From this it appears that the membrane disappeared on the average a little earlier than the bacilli, the figures being six and one-sixth days and seven days respectively, from the date of the first injection.

But the range of variation was very great, and the membrane was by no means always the first to disappear; it was only so in the *average* of the cases of recovery (that is, in the cases where it had full time for its evolution). The earliest date of the complete disappearance of membrane after the injection was one day, which was noted in one case; but in this the bacilli persisted for five days. In three cases the Klebs-Löffler bacilli lasted but one day after the injection, but in these traces of membrane persisted for three, four and five days respectively, after the injection. It was not uncommon for the bacteriologist to report a single swab as having no Klebs-Löffler when the next day's examination again revealed the organism. Hence the importance of requiring two consecutive negative reports before considering the case as well.

In a few instances a temporary interruption in the supply of material forced upon me a sort of control experiment. For example, a girl, aged two, entered January 14th. Had been sick five days. Serum was not at hand, and the membrane increased under observation till January 16th, when the material was obtained and she was injected. On the 18th both membrane and bacilli were absent, and she was discharged well on the 22d. A similar case was that of a boy, aged six, who entered December 26th. Sick two days, with a good deal of membrane, which grew steadily worse till the material arrived on the 28th, when he was injected. Six days later his membrane had disappeared, and he was up and dressed, though the bacilli persisted for fifteen days. A third child, a girl, aged eight, entered December 31st. Sick one day. She was profoundly septic; had membrane on the tonsils and pharynx; and no improvement occurred up to January 3d, when she was injected for the first time, and again on the 5th. The bacilli had disappeared on the 9th, but the membrane persisted till the 14th, and she was discharged well on the 16th.

Twenty-two of the cases were injected a second time, at an interval of one or two days from the first treatment. Seven of these reinjections were in patients who died. The reasons for such reinjections was failure of membrane to be thrown off, failure of a sharp line of demarcation about it, extension of membrane, and increase in the gravity of the symptoms.

Besides the 102 injections already accounted for, five more were made for purposes of immunization. Three were upon house-officers and two upon nurses, all of whom were coming into the wards for the first time or after a long interval. None contracted the disease, and all had a slight local dermatitis at the site of the puncture after a few days. One of the house-officers suffered from slight malaise and headache the day of the treatment. One patient, a girl of eleven, had received from a physician outside a prophylactic injection on the occasion of the appearance of another case of diphtheria in the household, and developed the disease exactly three weeks after the immunizing injection was given. It is well known that the immunity conferred by antitoxin is of comparatively short duration, and that on renewed exposure after three or four weeks, a new protection should be given. This I did not do in any of the five cases mentioned above.

A few words regarding the technique of the injections. The syringe used for the most part was of glass with asbestos packing of the piston which allowed the piston to be disinfected by fire while boiling water was used for the barrel and needle. This instrument proved more convenient than the Koch syringe which was employed at first.

As to the site, the interscapular region was at first made use of, but was speedily abandoned on account of the discomfort from lying on the seat of the puncture. A few injections were made in the flank, but the most advantageous place seemed to be the outer and front aspect of the thighs, which were not exposed to pressure; absorption was rapid. The skin at the site selected was prepared for injection by scrubbing with soap and water and later with corrosive solution. No pressure or massage of the tissues was practised. The puncture was closed with adhesive plaster.

The dose of Behring's solution was usually 10 c. c. of the No. 1 solution. The No. 2 and No. 3, of higher strength, were used in somewhat reduced doses, according to the gravity or especially the lateness of the case. The earlier doses of the Gibier solution were small — too small, 10 to 15 c. c. Later I used 20 to 25 c. c. of this, and if reinjection was employed about one-half the quantity.

The first good result from injection was usually seen within twenty-four hours in the form of a whitening and a dense milky color of the membrane, and its sharper line of demarcation. The exfoliation of membrane was generally most marked in the second twenty-four hours. A fall of temperature, although often occurring, seemed to be less significant than general improvement in the condition, for many of our worst cases of septic diphtheria have but slight temperature elevation.

Of unfavorable results from the injections the most annoying have been cutaneous eruptions. So far as I know no case of urticaria occurred after the use of the Behring serum which was employed in the first 20 cases, though this exemption may have been merely a coincidence. In the other 60 cases, 13 are known to have developed urticaria, in some of whom it was very severe and painful. As many patients were discharged early, in four to seven days after the injection, and as the urticarial affection does not appear often for a week or more, it is probable that a larger proportion had this skin eruption than the 21 per cent. who are known to have had it. A part of the difference in this regard between the two kinds of serum may have been due to the fact that larger volumes of the Gibier solution were injected than of the Behring.

Pain was complained of in several cases as being severe, both during and for hours following the injection, and also after several days' interval. The later manifestations were sometimes all over the legs and sometimes specially in the joints and of a rheumatoid character.

I could not satisfy myself that any cases of nephritis or endocarditis were attributable to the serum, as the proportion of these complications was not larger than is usual. Seventeen cases of the 80 showed signs of nephritis, being 21 per cent., which is not so large a proportion as occurred in my previous service under other methods of treatment.

The painful complications above noted will, I hope, disappear with greater perfection in the preparation of the material. With more moderate prices for the product the temptation will be less to the employment of horses which have a tendency to produce the cutaneous accidents, and the immunization of the animals can, when the hurry to "realize" on the product is less, be carried to a greater degree, so that the dose required for injection may be expected to become less. Finally, we may, I think, look for the time when the *true* antitoxin will be isolated from the blood-serum in which it is contained, and be employed in a smaller and more precise dose, with the total elimination of the cutaneous and other accidents which now constitute a drawback to serum therapy. Meantime, in the method as it stands, we have, as I believe, an achievement which in its beneficent results, is comparable only to the discovery of Jenner.

AN anti-cigarette league, representing 25,000 public-school boys in New York City, has been organized.

## A CLINICAL AND EXPERIMENTAL STUDY OF THE LEUCOCYTOSIS OF DIPHTHERIA.*

BY JOHN LOVETT MORSE, M.D.

(Continued from No. 10, p. 224.)

THE object of the first experiment was to determine whether a local diphtheria would cause a hyperleucocytosis.

RABBIT NO. 1.

October 24th. 9.30 A. M., white corpuscles, 5,800. 11 A. M., the palpebral conjunctiva of the left eye was excoriated over a small area and a pure, fresh culture of the Klebs-Löffler bacillus on blood-serum rubbed in. This culture was the second generation from a fatal case.

October 25th. 9.30 A. M., a spot of membrane, about one-quarter of an inch long and one-sixteenth of an inch wide, was present at the site of the excoriation. White corpuscles, 6,400.

October 26th. 10.30 A. M., membrane all gone. White corpuscles, 7,100. As the amount of membrane had been so small, and the increase of white corpuscles so slight as to be within the bounds of possible error, it seemed best to repeat the experiment. Accordingly, the conjunctiva was again excoriated at the same spot, but more deeply and over a larger area. 11.30 A. M., reinoculated with same culture.

October 27th. 10.15 A. M., excoriated spot covered with membrane over an area about one-quarter of an inch square, the membrane also extending a little onto the ocular conjunctiva which had not been irritated. White corpuscles, 9,100.

October 28th. 9.15 A. M., membrane a little less extensive. White corpuscles, 9,100. A blood-serum tube, inoculated from the eye at this time, twenty-four hours later showed a pure culture of the Klebs-Löffler bacillus.

October 29th. 12 M., membrane only about half as extensive. White corpuscles, 8,400.

October 30th. 9.30 A. M., membrane disappeared. White corpuscles, 8,200.

November 1st. 9.30 A. M., white corpuscles, 6,000.

The result of this experiment proves that a local diphtheria, produced by the Klebs-Löffler bacillus alone, is capable of causing a hyperleucocytosis. The results also agree in a general way with the conclusions arrived at clinically, namely, that the hyperleucocytosis varies with the amount of membrane and ceases soon after its disappearance.

A series of experiments was next undertaken to determine if the toxine produced by the Klebs-Löffler bacillus would alone, as seemed probable, cause a hyperleucocytosis.

RABBIT NO. 2.

October 31st. 9.30 P. M., white corpuscles, 12,400.

November 1st. 10 A. M., one-half a cubic centimetre of toxine solution injected into ear-vein.

November 2d. 9 A. M., found dead. A count of the heart's blood showed white corpuscles, 23,400. Autopsy showed inguinal, axillary, mesenteric and retroperitonea glands enlarged and reddened. Liver, macroscopically, showed no necrosis. Kidneys moderately congested. No fluid in thorax. Lungs somewhat congested and slightly edematous. Bone-marrow somewhat reddened.

RABBIT NO. 3.

November 2d. 12 M., white corpuscles, 6,700. 12.45 P. M., one-tenth of a cubic centimetre of toxine solution injected into ear-vein.

November 3d. 10.30 A. M., white corpuscles, 12,000.

November 4th. 10 A. M., white corpuscles, 16,300. At this time the animal was decidedly sick, showing marked

* A paper to which was awarded the First Lyman Prize for the year 1894. This paper will appear in the Medical and Surgical Reports of the Boston City Hospital, Sixth Series.

paresis of hind legs and some of front. 3.30 P. M., white corpuscles, 20,800. The rabbit was moribund at the time of this examination.

November 5th. 12 M., autopsy, rabbit having died during the night, showed axillary glands enlarged and reddened. Little or no enlargement and no injection of inguinal, mesenteric or retroperitoneal glands. Suprarenals much reddened. No macroscopic necrosis of liver. Kidneys much congested. No fluid in thorax. Lungs slightly congested, but not edematous. Bone-marrow very red.

In this case the leucocytosis had doubled in twenty-two hours and continued to increase steadily up to the time of death.

RABBIT NO. 4.

November 6th. 3.30 P. M., white corpuscles, 5,200. 4.30 P. M., one-fiftieth of a cubic centimetre of toxine solution injected into ear-vein.

November 7th. 9.30 A. M., white corpuscles, 8,400. 3.30 P. M., white corpuscles, 11,400. The rabbit was now evidently sick.

November 8th. 9.15 A. M., white corpuscles, 11,700. Rabbit much sicker. A differential count of the white cells made at this time, the height of the hyperleucocytosis, resulted as follows:

| | Per cent |
|---|---|
| Small Lymphocytes | 30.8 |
| Large Mononuclear and Transition Forms | 5.8 |
| Polynuclear Neutrophiles | 7.8 |
| Eosinophiles | 55.6 |

The consideration of this, as well as of the following differential counts will be taken up later.

November 9th. 9.30 A. M., white corpusules, 7,600. The rabbit was livelier than during the two previous days, and evidently on the road to recovery.

DIFFERENTIAL COUNT.

| | Per cent. |
|---|---|
| Small Lymphocytes | 41 |
| Large Mononuclear and Transition Forms | 10 |
| Polynuclear Neutrophiles | 11 |
| Eosinophiles | 38 |

November 10th. 9.30 A. M., white corpuscles, 4,000. Rabbit still improving.

November 17th. 9.30 A. M., white corpuscles, 5,800. The rabbit was now entirely well, but showed considerable induration about the seat of injection. It showed no signs of paralysis at any time.

In this case the increase in white corpuscles was well marked in seventeen hours, reached its maximum in forty-one hours, and had disappeared in eighty-nine hours. It is to be noted that the animal's condition varied with the leucocytosis, he being sickest when it was at its height, and improved as it diminished. It is also worth noting that the hyperleucocytosis disappeared before any local reaction manifested itself, which is in direct contradiction to v. Limbeck's theory.

The three preceding experiments seem amply sufficient to prove that the toxines alone are competent to produce a hyperleucocytosis. They also justify the conclusion that the hyperleucocytosis in diphtheria is due to the absorption of the toxic products of the Klebs-Löffler bacillus and varies directly with the amount of absorption.

It is probable, however, that clinically the toxic products of associated bacteria play a part in its production. The subsequent experiments, although undertaken for other purposes, emphasize the same points.

The next experiment was undertaken to determine whether the toxines of the Klebs-Löffler bacillus cause an initial hypoleucocytosis, and if so, the time of its appearance and its duration.

RABBIT NO. 5.

November 10th. 4 P. M., white corpuscles, 7,900.

DIFFERENTIAL COUNT, NORMAL BLOOD.

| | Per cent. |
|---|---|
| Small Lymphocytes | 45.2 |
| Large Mononuclear and Transition Forms | 6.6 |
| Polynuclear Neutrophiles | 11.2 |
| Eosinophiles | 37.0 |

November 11th. 9.15 A. M., Four-tenths of a cubic centimetre of toxine solution injected into ear-vein. 9.30 A. M., white corpuscles, 5,100.

DIFFERENTIAL COUNT.

| | Per cent. |
|---|---|
| Small Lymphocytes | 32.2 |
| Large Mononuclear and Transition Forms | 7.6 |
| Polynuclear Neutrophiles | 8.9 |
| Eosinophiles | 51.3 |

10.30 A. M., white corpusules, 4,900.

DIFFERENTIAL COUNT.

| | Per cent. |
|---|---|
| Small Lymphocytes | 31.2 |
| Large Mononuclear and Transition Forms | 7.4 |
| Polynuclear Neutrophiles | 11.2 |
| Eosinophiles | 50.2 |

11.45 A. M., white corpuscles, 7,300. 3.30 P. M., white corpuscles, 13,100.

November 12th. 9.15 A. M., white corpuscles, 11,500. The animal at this time, although not well, showed no very marked symptoms.

November 13th. 9 A. M., found dead, but warm.

At the autopsy the axillary glands were slightly enlarged, but not much reddened. No enlargement or injection of inguinal, mesenteric or retroperitoneal glands. Supra-renal capsules moderately reddened. No macroscopic or microscopic necrosis of liver. Kidneys much congested. No fluid in thorax. Lungs moderately congested, but not edematous. Bone-marrow very red.

As is evident above, the result of this experiment is positive, a definite hypoleucocytosis being present fifteen minutes after the injection. The lowest point was reached in an hour and a quarter. One and one-quarter hours later the number had nearly returned to normal, and three hours after this there was a marked hyperleucocytosis. The differential counts will be considered later. In "Rabbit 7" also, a marked hypoleucocytosis was present in half an hour.

The existence of hyperleucocytosis and hypoleucocytosis having been demonstrated, a series of investigations was begun to determine, if possible, the nature of the processes, and to determine also which, if any, of the theories detailed above was tenable. The best way of getting at this seemed to be to kill animals during the various stages and then to make careful microscopic examinations of the organs, paying especial attention to the distribution of the white cells in them and to the bone-marrow.

The animals were killed by a sharp blow on the back of the neck, immediately autopsied, and the organs removed with as little handling as possible and placed in a saturated solution of corrosive sublimate in normal salt solution. After hardening in this for twenty-four hours they were washed in running water for twenty-four hours, then placed in absolute alcohol and mounted in celloidin in the usual manner. The sections were all cut of the same thickness in order to avoid error. Sections of the femur were made in the normal rabbit and in one killed during hyperleucocytosis and kept in absolute alcohol for ten days. The outside bone was then removed and the marrow placed in five-per-cent. nitric acid for twenty-four hours. It was then washed and mounted in celloidin as were the other organs. Cover-slips were also made from the fresh bone-marrow and hardened in alcohol and ether.

### RABBIT NO. 6.

A normal rabbit killed for purposes of comparison. It is noteworthy that the bone-marrow of the rabbit is extraordinarily rich in eosinophile cells, they forming the very great majority of the white cells present there.[14]

### RABBIT NO. 7.

Killed during hypoleucocytosis.

November 15th. 10.30 A. M., white corpuscles, 7,300. 11.15 A. M., seven-tenths of a cubic centimetre of toxine solution injected into ear-vein. 11.45 A. M., white corpuscles, 4,500. 12.15 P. M., killed.

At the autopsy no macroscopic changes were recognizable. Bone-marrow yellowish-red. Microscopical examination of specimens of the liver and kidney, stained with saffranin, showed no abnormal changes. There was no congestion and no increase in the number of white cells in their capillaries. Sections of the lungs were stained both with saffranin and with Ehrlich's "triple-stain," the latter giving a most beautiful differentiation of the white cells. These sections were carefully compared with those of the normal lung prepared in the same way. It must be admitted here that the conclusions arrived at are founded entirely on individual estimation and judgment, it being impossible to count the cells.

Drs. Councilman and Mallory, however, who were shown the specimens from the three cases, without being told which was which, arrived at the same conclusions regarding the number of white corpuscles as myself. While there was no noticable increase in the number of red corpuscles in the lung capillaries, the white cells were very much more abundant than in the normal lung. In the large blood-vessels, however, the white corpuscles were much diminished. It was impossible to tell whether any one kind of white cells was more than proportionately abundant, the general impression being, however, that the proportions were about normal. Numerous hyaline thrombi were present in the lungs.

### RABBIT NO. 8.

Killed during hyperleucocytosis.

November 18th. 11 A. M., white corpuscles, 12,700. 11.45 A. M., two-tenths of a cubic centimetre of toxine solution injected into ear-vein.

November 19th. 9.30 A. M., white corpuscles, 29,200.

DIFFERENTIAL COUNT.

| | Per cent. |
|---|---|
| Small Lymphocytes | 15.4 |
| Large Mononuclear and Transition Forms | 1.6 |
| Polynuclear Neutrophiles | 4.4 |
| Eosinophiles | 78.6 |

11 A. M., killed.

At the autopsy the axillary, inguinal, mesenteric and retroperitoneal glands were unchanged. Supra-renals much reddened. No macroscopic necrosis of liver, which was somewhat congested. Kidneys much congested. Urine not hemorrhagic. No fluid in thorax. Lungs moderately congested, but not edematous. Bone-marrow yellowish-red, but no redder than normal.

Microscopic examination of sections of the liver, stained with saffranin, showed marked congestion. The increase in white cells did not seem out of proportion to the increase in red, when the hyperleucocytosis was taken into consideration. Double-staining with eosin and methylene-blue failed to show any necrotic areas. Sections of the kidney, stained with saffranin, showed an enormous congestion. The increase in white cells, however, was not out of proportion to the hyperemia and hyperleucocytosis. Sections of the lungs were prepared as in the previous cases. There was a decided increase in the number of red cells in the capillaries. The white corpuscles seemed less abundant in the capillaries than during hypoleucocytosis. They were more numerous than in the normal lung, however, and seemed to be in larger numbers than the congestion and general hyperleucocytosis would explain. The impression obtained was that the eosinophile cells were more than proportionately abundant. The white cells in the large blood-vessels seemed about proportionate to the red corpuscles, when the general hyperleucocytosis was taken into consideration. Numerous hyaline thrombi were present in these lungs also.

Specimens of the bone-marrow stained with saffranin and compared with the normal showed a diminution in the number of polynuclear cells and giant cells; nuclear figures, however, were much more abundant. Those stained with "triple-stain" also showed a diminution in the number of giant cells. There was a great increase, however, in the number of small cells with small, round, deeply-staining nuclei and a marked increase in the nuclear figures in these same cells. I am unable to give any explanation of the significance of these cells or of the change in them.

The object of the last experiment was to determine whether there was the same increase in the number of erythrocytes during experimental hyperleucocytosis as appeared clinically. The corpuscles in five cubic millimetres were counted at each examination.

### RABBIT NO. 9.

December 1st. 3.45 P. M., red corpuscles, 6,075,200; white corpuscles, 8,800; white to red, 1,690. 4.15 P. M., two-tenths of a cubic centimetre of toxine solution injected into ear-vein.

December 2d. 9.30 A. M., red corpuscles, 7,436,400; white corpuscles, 12,400; white to red, 1,600.

That is, there was an increase in the number of red corpuscles of a little more than 20 per cent., thus confirming the clinical observations. As stated, when considering the clinical examinations, I am unable to find any satisfactory explanation for this increase.

December 3d. 10 A. M., rabbit moribund. Circulation so feeble that no blood could be obtained from ear.

December 4th. 9 A. M., died during the previous afternoon.

At the autopsy the axillary glands were moderately enlarged and reddened; inguinal glands less so; mesenteric and retroperitoneal not at all. Supra-renals moderately reddened. Liver moderately congested, but showed no macroscopic necroses. Kidneys much congested. No fluid in thorax. Lungs moderately congested and edematous. Bone-marrow no redder than normal.

The results of my experiments coincides pretty closely with those obtained by Goldscheider and Jacob. They show that hyperleucocytosis occurs without local inflammation or exudate, and that, experimentally at any rate, hyperleucocytosis is preceded by hypoleucocytosis. The presence of an increased number of white cells in the lung capillaries during hypoleucocytosis, and to a less extent during hyperleucocytosis, is in direct contradiction to Löwit's theory of leukolysis. The absence of an increase of white cells in the liver and kidney during hypoleucocytosis and the persistence of an increased number in the lung capillaries during hyperleucocytosis prove that Schultz's supposition that hypoleucocytosis and hyperleucocytosis are merely the expression of a shifting of leucocytes is wrong.

As already noted, my results were the same as those obtained by Goldscheider and Jacob, except that I found rather fewer leucocytes in the lung capillaries during hyperleucocytosis than during hypoleucocytosis. This is a comparatively unimportant difference, however, as there are so many more there than in the normal lung that it is evident that at least only a part of the cells can have returned to the general circulation, and hence that the white cells in the general circulation during hyperleucocytosis must be largely new accessions from the blood-forming organs; that is to

say, my results corroborate the chemotaxic theory and seem explicable by it alone.

Everard concludes that there is a special diminution in the polynuclear cells with granular protoplasm during hypoleucocytosis, and that these same cells are very abundant during hyperleucocytosis. Löwit and Goldscheider and Jacob found almost exclusively mononuclear cells immediately after hypoleucocytosis, and that a decided preponderance of polynuclear cells arises during the course of the hyperleucocytosis. The proportions of the white corpuscles in the rabbit differ decidedly from those in man. The average of the differential counts made in the normal rabbits is as follows:

| | Per cent. |
|---|---|
| Small Lymphocytes | 43 |
| Large Mononuclear and Transition Forms | 8 |
| Polynuclear Neutrophiles | 11 |
| Eosinophiles | 38 |

That is, there are twice as many small mononuclear cells as in human blood while the polynuclear neutrophiles, which make up the bulk of the white cells in human blood, here form but a small factor. The eosinophile cells, however, are very much more numerous, making more than a third of the total. They probably correspond to the polynuclear neutrophiles in the human blood and represent the oldest forms. Attention has already been called to their extreme abundance in the normal marrow. Two counts made during hypoleucocytosis (Rabbit 5) resulted as follows:

| | Per cent. | |
|---|---|---|
| Small Lymphocytes | 32.2 | 31.2 |
| Large Mononuclear and Transition Forms | 7.6 | 7.4 |
| Polynuclear Neutrophiles | 8.9 | 11.2 |
| Eosinophiles | 51.3 | 50.2 |

That is, there was a diminution in the small mononuclear cells and a proportionate increase in the polynuclear eosinophiles, which is directly the opposite of Everard's observation. No count was made at the beginning of hyperleucocytosis. One made at its height (Rabbit 8) resulted as follows:

| | Per cent. |
|---|---|
| Small Lymphocytes | 15.4 |
| Large Mononuclear and Transition Forms | 1.6 |
| Polynuclear Neutrophiles | 4.4 |
| Eosinophiles | 78.6 |

Another made during the subsidence of hyperleucocytosis was as follows:

| | Per cent. |
|---|---|
| Small Lymphocytes | 30.3 |
| Large Mononuclear and Transition Forms | 5.8 |
| Polynuclear Neutrophiles | 7.8 |
| Eosinophiles | 55.6 |

This agrees entirely with the results of other observers, and is undoubtedly the analogue of the increase in polynuclear neutrophiles in man. Goldscheider and Jacob lay much stress on this large proportion of eosinophiles, and consider that they are not entirely formed from the new mononuclear cells, but are partly old cells which were lying in the bone-marrow ready for extrusion, and have been brought into the circulation in increased numbers by chemotaxic action. A careful study of slips made from the fresh bone-marrow was very unsatisfactory. The impression obtained, however, was that the eosinophile cells were less plentiful in the marrow of hyperleucocytosis than in the normal. As mentioned above, the cut section of the marrow of hyperleucocytosis showed a diminution in the number of polynuclear cells. These observations, as far as they go, agree with Goldscheider and Jacob's position, that the increase in the eosinophiles is partly the result of the extrusion of the cells already formed in the marrow, and confirm the chemotaxic theory.

The gross pathological lesions observed in the five animals autopsied during hyperleucocytosis are of some interest. In one case there was no involvement of the lymph-glands. In all the others the axillary glands were enlarged and more or less congested, while the inguinal were affected in two, and the mesenteric and retroperitoneal in only one. The supra-renal capsules were involved in every case, being moderately reddened in three and much in two. The kidneys were enormously congested in four cases, and moderately so in one. The liver was slightly congested in two, not at all in the remainder. No macroscopic necroses were observed and none were found in the two cases examined microscopically. The thorax never contained fluid. More or less congestion of the lungs was present in every instance, however, and in two there was slight edema. The bone-marrow was redder than normal in three cases.

To sum up, the constant and most striking lesions were congestion of the kidneys, supra-renals and lungs. More or less acute lymphademitis was usually present, and occasionally edema of the lungs and reddening of the bone-marrow. Necrotic foci in the liver and fluid in the thoracic cavity, which were found so frequently by Wright[15] in guinea-pigs dead of experimental diphtheria, were not observed.

When my work was nearly completed, a paper was published by Gabritschewsky[16] entitled "Du Rôle des Leucocytes dans l'Infection Diphterique." He investigated the general leucocytosis of diphtheria in children and rabbits, and in addition studied the local leucocytosis and the action of the antitoxin serum on the progress of the leucocytosis. His conclusions regarding the general leucocytosis, based on his observations on fourteen children and on rabbits, are as follows: There is always a hyperleucocytosis in diphtheria, which is greatest in the fatal cases, and which progressively diminishes during convalescence and after injections of antitoxin. A progressive hyperleucocytosis in diphtheria justifies a bad prognosis, and the analysis of the blood gives useful information regarding the value of treatment. He found that the number of white cells ordinarily varied between 11,450 and 25,000, and in fatal cases between 29,500 and 51,000.

### LEUCOCYTOSIS IN POISONING BY ILLUMINATING GAS.

BY RICHARD G. EATON,
*House-officer, Boston City Hospital.*

IN view of the attention which is being given to the presence and signification of leucocytosis in various pathological conditions, I venture to report, with the permission of the Visiting Physician, the results of the blood examinations in four cases of poisoning by water-gas, occurring recently at the City Hospital.

CASE I. Male, twenty-one, single. Entered on the morning of October 7th, in an almost unconscious condition. He had been drinking the night before, and returned to his room some time after midnight. In the morning he was found unconscious, with a strong odor of gas in the room and the gas turned on. He was brought to the hospital. An examination of his blood at that time showed roughly an apparent increase in the neutrophylic leucocytes and poikilocytosis. A careful count of the blood gave an average of 4,000,000 red and 22,000 white corpuscles to the cubic centimetre. The patient recovered consciousness in a few hours after entrance, and was discharged well in a few days. Blood-counts were made in the instance of three other gas-poisoning cases on the service, as the leucocytosis observed in the first case was considered of sufficient importance to make a record of it. The three following cases also showed a leucocytosis varying from 15,000 to 19,000.

CASE II. Female, twenty, single. Entered the hospital November 10th, having been in an unconscious state for eight hours. An examination and blood-count was made on the following day, the blood being very dark when drawn. The leucocytes numbered 15,000.

CASE III. Male. Entered November 15th. Unconscious, cyanotic, and with an odor of gas in his breath. A blood-count showed 19,000 white corpuscles. On the following day another count was made, the whites numbering 18,000, and the reds 4,000,000.

CASE IV. Female, sixty, married. Entered November 18th. Was unconscious and somewhat cyanotic, with an odor of gas in her breath. A blood-count was made on the following day, when the whites numbered 18,000, and the reds 4,810,000; hemoglobin was 96 per cent. The patient recovered from the effects of the gas-poisoning and was discharged.

## Medical Progress.

### RECENT PROGRESS IN PATHOLOGY.

BY W. T. COUNCILMAN, M.D.

#### THE ETIOLOGY OF CARCINOMA.

MOST of the recent articles on the etiology of carcinoma refer it to organisms belonging to the protozoa.

Since the last report on this subject in the Boston *Medical and Surgical Journal*, many new articles have appeared. One of the most important is a collective report by Stroebe in the *Centralblatt f. Allgeimeine Pathologie*, in January, 1894. In this article a critical review is given of the most important publications on the parasitism of carcinoma which have appeared in the last three years.

In the beginning of the article Stroebe refers to publications on the diseases of animals supposed to be due to parasites belonging to the sporozoa. One of the most important works on this subject is that of Pfeiffer. He has investigated affections of animals and of man in which sporozoa have been found, and has embodied the results of his investigation in an extensive monograph accompanied by an atlas filled with photo-micrographs. In almost all of these diseases the epithelial structures are involved, and the lesions consist essentially in hypertrophy and hyperplasia of the cells. Pfeiffer has also described certain affections of the voluntary muscles in various animals, especially in fish. In the latter the nerves may be affected and the disease may appear as a parasitic polyneuritis. Invasion of the red blood-corpuscles by the sporozoa is seen in birds and mammals. The classification of the sporozoa is very indefinite. Pfeiffer follows the classification of Butschli, who has divided them into the gregerina, the coccidia, and the sporidia. The best known among the coccidia is the coccidium oviformis, which is a common parasite of the liver of the rabbit. The sporidia are further divided into the sarco-sporidia, the micro-sporidia and the myxo-sporidia. Many of these exist as parasites in the muscles. As a further division Pfeiffer makes a class of hemo-sporidia, to which belong the blood parasites in the frogs, in birds and in man.

With regard to the development of coccidia and sporidia, he shows that there is a protoplasmic youthful form resembling a naked cell which grows to a considerable size and then becomes encysted. The protoplasmic masses within the capsule segments into a number of bodies, the so-called sporo-cysts, or spores of the first order; and in the interior of these small boat-shaped bodies the typical spores develop. He shows that the number of the spores in the sporoblast is characteristic for the different species. From these spores the protoplasmic youthful form can develop. The organism does not always go through these different stages. The stages of development are frequently shortened, and in many species some of the stages are wanting. Most of the phases of development of the parasitic sporozoa are met inside of the host, whereas others take place outside.

In the work of Pfeiffer there are a number of interesting observations. There can be little doubt that in many cases the conditions which he describes are due to parasitic sporozoa, and there can be equally no doubt that in many cases he has described and depicted conditions in cells which have nothing to do with parasites. Steinhause has described a condition in the cells of the alimentary of the salamander probably due to a sporozoic parasite. This develops in the nucleus of the cell, and devours the nuclear substance. Pfeiffer has also given a careful description of the coccidial disease which appears in the liver and intestine of rabbits. The disease is a very common one, and in the liver the parasites can be easily demonstrated in the epithelium of the bile-ducts. These produced hyperplasia of the bile-ducts leading to more or less extensive capillary ingrowths of the epithelium, which appeared as tumor-like masses in the liver. In its youngest form the parasite appears as a round protoplasmic mass of about the size of red blood-corpuscles with vesicular nucleus, which does not stain with the

ordinary nuclear stains. These bodies are found partly free in the contents of the bile-ducts, partly in the epithelium of their walls. In the course of development, which is exclusively intra-cellular, the parasites press to the foot of the cylindrical epithelial cell, greatly distending it. It then becomes granular, and surrounded with a double-contoured membrane. It has been known that these oviform coccidia grow outside of the body of the host, but Pfeiffer was the first to discover its inter-cellular growth. This oviform structure divides into four round or ovoid structures which are also surrounded by a membrane, and these divide each into two sickle-shaped spores which represent again the youthful form. In some cases segmentation of the parasite can take place without the preceding stage of encysting. It then divides into a number of sickle-shaped structures which become surrounded by a membrane, as the skin of an orange surrounds the segments. The infection of the rabbit takes place by these ripe cysts filled with spores, being taken into the stomach with food. The membrane of the cysts are softened by digestion, and the spores having become free enter into the intestine or liver. These organisms, or organisms similar to these, have been found in affections of the intestines of young sheep and in other places.

When we leave this simple disease of animals and take up what has been written concerning the supposed coccidial affections in man, we come to much more uncertain ground. They have been described in the affection known as Darier's disease. In this the pathological condition consists in the formation of small foci of hyperkeratosis, producing small elevations distributed over almost all parts of the body. According to Darier and White, the abnormal keratosis takes place from the ducts of the hair-follicles. In the neighborhood of the small foci there is increased pigmentation of the reti, the epithelial cells of the horny layer are loosened, frequently separated by fissures, and the cutis shows slight inflammatory changes. Darier has described in the horny layer of the skin peculiar structures which he regards as psorosperms, and which he thinks can be distinguished from the epithelial cells. The views of Darier on the parasitic nature of these structures are opposed to Bowen, who studied the histological changes in the disease. At present most of the authors who have investigated this disease are inclined to refer the supposed parasites to abnormal processes of cornification.

The epithelioma contagiosum has long been considered as due to a parasite. The disease appears in the form of small nodules of about the size of a pea, with a central depression. On section it has a distinctly lobular form due to the epithelial masses which extend out from the central depression. Peculiar highly refractive bodies are found in the central depression, and in the masses of epithelial cells. In 1888 Neisser described a supposed parasite in this affection, and considered it as belonging to the coccidia. Torok opposed this view, and considers the molluscum bodies as the product of degenerative processes in the epithelial cells. He considers them, on account of their great resistance to chemical changes, as probably formed of a colloid substance, and thinks that they should not be considered as animal parasites until evident signs of development or proliferation can be made out in them. Zeigler regards the parasites as probably belonging to the coccidia, and the cause of the peculiar growth of the epithelium. He describes as the youthful forms of the parasites, round protoplasmic structures, lying in the epithelial cells beside the nucleus. The parasite is at first difficult to distinguish from the cell protoplasm, but later shows small, distinct granules in its interior which grow out to large bodies. The whole parasite increases in size and takes up almost the entire cell, pressing the nucleus to one side.

When we take into consideration all the views which have been held as to the character of the molluscum bodies, it appears evident that the authors who regard them as non-parasitic in character have rather the best of the argument. No certain proof of their parasitic character has ever been given. They are simply peculiar bodies which stain differently from the rest of the epithelium. Eleidine and other constituents of normal epithelial cells have been made out in them, and they are most probably epithelial cells which have undergone some peculiar form of degeneration. The results of inoculation show that the affection is contagious, but the contagion may be due to something else than the molluscum bodies.

Under the name of epithelioma follicularis cutis, Israel has described a peculiar form of tumor very similar to molluscum contagiosum, and in this he has found structures similar to the moluscum bodies. The formation is an epidermoid tumor of benign character, and which appears on those parts of the skin which are covered with hair. The surface of the tumor is covered with a thin layer of epidermis, and there are crater-like openings which pass in the interior. These depressions which are due to enlarged and deformed hair-follicles give the tumor an irregular surface; and he considers it a retention tumor, with proliferation of the surrounding epithelium. In the epithelial covering the depressions, structures in every way similar to the molluscum bodies, are found in great numbers. He does not regard it as certain that they are parasites, although he says that many of them correspond to certain forms found in the various stages of development of the sporozoa.

In Paget's disease of the nipple, structures of a similar character have been described. In this affection there is an early stage similar to eczema. This produces a superficial ulceration with depression of the nipple, and sometimes, after years, a typical epithelioma develops. Darier, Wickham and Malassez regard this affection as parasitic and due to living sporozoa in the epithelial cells, but this view has been opposed by various authors. Affections in some respects similar to Paget's disease have been described in other parts of the body. Pick has reported a similar condition arising in the glans penis. In the epithelial growth of this he found numerous bodies similar to the psorosperms described by various authors. Ruffer and Plimmer found in two cases of Paget's disease a supposed form of parasite different from that described by Darier and Wickham, and similar to the forms found by these authors in carcinoma and considered by them as parasitic. These supposed parasites were not found where the affection had an eczematous character, but in the epithelial cells of the parts in which the distinct carcinoma had developed. Neisser, who regards the parasitic character of the molluscum bodies as certain, expresses himself cautiously about Paget's disease. On the other side, the

proof which would be given by differences in staining, that the structures are parasitic, is wanting. Further, the regular localization of the affection in the female breast does not speak in favor of its parasitic nature. In the metastases of the carcinoma developing from this, Neisser was not able to find the supposed parasites. Karg, who has investigated the affection carefully, does not consider the structures described as parasites. He thinks that the disease in the very beginning is an epidermoid carcinoma.

When we review what has been given here it is seen that strict proof of the parasitic nature of the bodies described in these affections has not been given, and for some of them it is very probable that they are altered epithelium. We could divide the four affections into two groups: one in which the molluscum contagiosum and the epithelioma follicularis could be placed, and in the other Darier's disease and Paget's disease. The proven infectiousness of the molluscum contagiosum, the peculiar position and shape of the structures described in it, and their similarity to some of the known forms of the sporozoa would incline one to consider them as parasitic in character. It is possible, however, that they may be altered or degenerated epithelial cells and the infectious matter may still be undiscovered.

A great number of publications have appeared on the supposed sporozoa found in carcinoma. New forms of the supposed parasites are constantly being described and many articles have appeared, some speaking for, and others against the parasitic nature of these structures. The appearances described by the different authors are of a very different character; and almost all appearances in the cells, which with our present knowledge cannot be well explained, have been regarded as parasites.

Steinhause has carefully investigated these appearances in the carcinoma cells, and thinks that they are to be referred to a number of conditions. They may be due to leucocytes which have become enclosed in the bodies of the epithelial cells, and these undergo degeneration, or partial cornification of cells, or to inclusion of one cell, or part of a cell in another cell. In 95 carcinomas of various sorts Soudakewitch found structures which, on account of their morphological characters, he considers identical with the parasitic sporozoa. Frequently several of the supposed parasites were included in the same cell. They were found in the hypertrophied cells, and even in those which showed nuclear division. He does not think that the multiplication of cells is produced by the parasites, but it is not retarded by their presence. Where destruction of the cell is due to the parasite, it is in consequence of the atrophy of the nucleus from the pressure exerted by the growing parasite. Finally the cell bursts and the parasite is free, and other cells may be infected. When the cell containing several parasites divides, then each of the daughter cells may contain the parasites. Metschnikoff confirms the observances of Soudakewitch, and thinks that these structures are most probably coccidia. He has found forms of parasites in carcinoma which show a remarkable similarity with certain stages of development of the oviform coccidia in the rabbit's liver. Podwissoki and Sawtschenko have found sickle-shaped structures in 20 carcinomas from different organs, which they considered as parasitic. Foa found in 70 carcinomas, most of which were in the mammary gland, structures enclosed in cells, which he regards as parasites. As the earliest stage of the development of the parasite, he describes small, round, oval, vesicular bodies, which were frequently contained in great numbers in the protoplasm of the cancer cell. In the vesicles there is an irregular central body which is colored a dark blue with hematoxylin, and divided into segments by lines radiating from the centre to the periphery. These structures may be so large that the nucleus is pressed to one side. He thinks that the presence of these parasites in the cells is not accidental, but they stand in a causal relation with the development of the carcinomas. In a second publication on the subject he remarks that the interest of the investigators has centred on certain forms of cell-inclusion which have nothing to do with degenerative products, but which are most probably parasitic in character. In sixty different tumors investigated by him about one-third show clearly the parasites. Almost every form of the tumor shows a special form of parasite. In the places where cell-division was going on most rapidly the parasites were most numerous.

*(To be continued.)*

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. G. MUMFORD, M.D., SECRETARY.

REGULAR Meeting Monday, January 7, 1895, DR. C. J. BLAKE in the chair.

#### ANATOMICAL SPECIMENS.

DR. HOMANS: I have here a fibroid consisting of two principal lobes with the body of the uterus between them, that is, dumb-bell shaped. The patient was a single woman, thirty-two, thin and suffering from pelvic pain and from constipation; otherwise pretty well, but as I had seen one patient with a fibroid filling the bony inlet of the pelvis and compressing the rectum, I thought it was well to remove this tumor. This woman did remarkably well, had no rise of temperature. There was one peculiar thing about her, a susceptibility to morphia. The family was said to be remarkably susceptible to morphia, and as I always give my patients morphia subcutaneously before etherization, I was careful to give this patient only one-sixteenth of a grain at nine o'clock. At two o'clock I was called to see her, and her respirations were seven per minute, her face dusky, and she was evidently very deeply narcotized. She was given one-sixtieth of a grain of atropia, and in the course of an hour or two the respirations rose to sixteen or seventeen and she recovered well. But I never saw morphine poisoning from one-sixteenth of a grain of morphia before.

DR. S. L. ABBOTT related

#### A CASE OF EMBOLISM OF THE FEMORAL ARTERY.

DR. JOHN HOMANS read a paper on

#### THE SURGICAL TREATMENT OF UTERINE FIBROIDS.[1]

DR. BAKER: I have been very much interested in Dr. Homans's paper. I am very glad indeed to hear

[1] See page 221 of the Journal.

that Dr. Homans has given up the method of extra-abdominal treatment of the stump. It always seemed to me to be rather an unsurgical method, although I never used it but once. It seems to me we have gone through, in the treatment of the stump, very much what was gone through years ago in regard to ovarian cysts. We remember when Sir Spencer Wells was treating the pedicles of ordinary ovarian cysts outside of the body with a clamp, and it seems to me it is a great advance in the treatment of fibroids by the intra-abdominal method. And I quite agree also with Dr. Homans in his make-up of the class of cases of fibroids that require operation. It seems to me his draft of those causes was exceedingly well made. I am also glad to see he uses the braided silk in preference to the catgut for these cases. I was talking a short time ago with Dr. Kelley of Baltimore, and that is what he makes use of entirely in those cases. It seems to me there are certain advantages to be gained sometimes in the removal of fibroids by preceding the operation by thorough curetting of the uterus and the thorough cleansing of the vagina, inasmuch as we cannot always tell in advance what case may require opening of the vagina and perhaps removal of the entire uterus. Certain it is that some cases seem to be better treated by the removal of the whole uterus, and even in the cutting off the uterus, as Dr. Homans has described, I think that preceding the operation with thorough curetting of the uterus will give a little better chance to do a clean operation, and prevent any sepsis from the wound, and not trust entirely to the use of the cautery for that purpose.

My experience in the removal of the ovaries and tubes for the disappearance of fibroids would teach me to take a little exception to what Dr. Homans has said in the matter of its being unreliable. In a limited number of cases, perhaps ten or twelve, where I have removed the ovaries and tubes for the disappearance of the fibroid it has been exceedingly reliable: but it is only right to say that I should choose for that operation a fibroid where the uterus and the fibroid together were not larger than the uterus at three or three and a half months of pregnancy. I should not hope to cause a disappearance of a large fibroid by the removal of the tubes and ovaries although it might sometimes occur; still I think in the small fibroids, if not larger than the gravid uterus of three or three and a half months, it would be found to be more reliable than perhaps Dr. Homans has intimated.

I do not know of anything that requires a more careful exercise of judgment than to know what to do with an individual case of fibroid, so many things have to be considered; and I think as we go on and see more and more cases, we are perhaps all the more at a loss to know exactly what advice to give in any individual case. I think Dr. Homans expressed it very well indeed: "If it is so large and for reasons of delicacy of feeling of a single person, or if by its pressure it is accomplishing so much harm, it is a case to be operated upon." But it is surprising sometimes to see what an amount of disturbance even a small fibroid will make. In the case Dr. Homans showed to-night, the size of which is nothing like some of the large fibroids he has shown here, the disturbance from it was undoubtedly so great as to necessitate its removal; therefore I do not think you can always reason from the size of the fibroid that it would or would not necessitate an operation. I showed to this Society within two years quite a small fibroid that caused such an amount of disturbance, both nervously and of the rectum, that it necessitated its removal, and this was accompanied by perfect relief.

I think we all should thank Dr. Homans most heartily for the very interesting paper which he has presented to us to-night.

Dr. Richardson: I have followed the teachings of Dr. Homans in the treatment of fibroids as I have in the treatment of ovarian tumors, looking to him as the pioneer of abdominal surgery in this community, and adopting in almost every respect his methods of treatment. I feel more inclined to operate on fibroids now than I did, because in two of my cases the operation has been seriously, I may say fatally, complicated by abscess. In fact, the only deaths that I have had in the last two years after hysterectomy for fibroids have been caused by pus in the posterior cul-de-sac, this combination demanding operation when the conditions were most unfavorable. The patients were much reduced in strength. The fibromata, fixed in the pelvis by extensive inflammatory exudations, caused the phenomena of incarceration. The operations were performed as a last resort, and both were fatal.

I feel so safe now in abdominal hysterectomy, practically by the same method which Dr. Homans describes, that I advise the operation for pain that does not yield to treatment, for persistent hemorrhage, for rapidly growing tumor. The operation of abdominal hysterectomy, it seems to me, is one of the most beautiful in abdominal surgery. I am rather inclined to remove the cervix with the tumor, in order to get drainage in that small space enclosed by the inverted peritoneal edges, fearing that the uterine canal may not be large enough for this purpose. In my experience there has always been, between the layers of the broad ligament about the stump of the uterus, abundant oozing, which can escape only by the cervical canal. I do not think that it adds much to the dangers of the operation to remove the whole of the uterus. I have not done this except in cancer, but it seems to me that in the future I shall try to make this thorough extirpation. I have been interested in everything that Dr. Homans has said as to technique, especially with reference to the bladder. I think that we cannot be too careful in looking out for some abnormal position of the bladder, especially if the tumor is a large one. One case I recall especially — I think Dr. Homans will remember it — in which the bladder had been stretched so that it was apparently attached to the posterior and upper part of a large uterine fibroid. It is not surprising that in removing the tumor a large opening was made in the bladder. This was immediately closed, and, like all the wounds which I have made accidentally in the bladder during abdominal operations, seemed to add nothing to the risk. In one instance I have removed from the female bladder a stone which had formed upon the knots by which a bladder wound, made accidentally by another surgeon in a hysterectomy, had been closed. Not that that is a very serious matter; but if the bladder had not been opened, the stone would not have formed.

Dr. Conant: I have been extremely interested in this paper, and I wish to thank Dr. Homans for showing the way to so many of the younger men who have been attempting to follow in his footsteps. It is some-

thing like two years since I first did a hysterectomy by this method, with this modification; in every case but one, of taking out everything, leaving only the vagina. That one case was fatal. I do not know whether it had anything to do with the fact that the whole cervix was not taken out or not, but that is the only case, except one other of recent date which was of immense size and done as an emergency operation rather against my wishes, but at the request of the patient. The patient did not recover from the operation. With the exception of these two cases, as far as I remember now, every case for fibroid that I have done by hysterectomy has done well, and I have had twenty-one cases in all; and I have preferred this method. I never have used the extra-abdominal method.

I understand that there has been some criticism about removing the cervix, because you do not thereby get as good support. In a certain number of cases where I have removed the cervix I have attempted to get that support by sewing up the top of the vagina and sewing the peritoneum over that, and I have yet to see a case that does not present support enough for all practical purposes.

I should agree with Dr. Richardson, that I am much more inclined to operate on fibroids than Dr. Homans would seem to be. I have had in my own family a case I took to Dr. Homans a number of years ago; and he advised the patient, unless there was some trouble, not to have the tumor removed. That young woman has never had what you call a great deal of trouble, but has been a confirmed invalid from that time to this. She has to keep quiet from ten to fourteen days in every month, unable to take active exercise; and judging from that case and several others I have seen, I am inclined to operate on a case that is not even causing a great deal of discomfort, believing that the result gained is very much superior to the amount of risk. I believe that the operation as described by Dr. Homans is almost absolutely safe, provided the patient is healthy and the tumor not excessively large.

I agree with Dr. Homans as to the necessity of perfect antisepsis. And yet this summer I did an operation on a sloughing fibroid in a woman over seventy in a very bad condition generally from sepsis, and having had just before I planned to operate a very severe hemorrhage stopped by perchloride of iron by the vagina. The next morning the operation was performed; there was no rise of temperature; recovery in three weeks. I had no expectation that the woman had any chance of recovery, and it was done as an emergency operation.

I think this operation we can safely commend as one which offers great relief to a set of annoying symptoms, and it can be done with safety and with celerity. One who has never done it is surprised at the celerity with which it can be done by an experienced operator; thirty-five to forty-five minutes is an average time, and I have seen it done in less time than that. Considering the character of the operation that is a remarkably short time, and the shock is usually very slight. If there is no sepsis the patient has almost no reaction, oftentimes no rise of temperature.

---

REGULAR Meeting, February 18, 1895, the President, DR. CLARENCE J. BLAKE, in the chair.

DR. C. F. WITHINGTON read a paper on

THE ANTITOXIN TREATMENT OF DIPHTHERIA.[1]

DR. MASON: I had the pleasure of seeing a considerable number of Dr. Withington's cases, and it is quite evident that his report shows a very careful and painstaking use of this new agent. The results are certainly gratifying. I took charge of the diphtheria ward for a short time myself, and observed a certain number of cases of the same kind. I can add little to what Dr. Withington has said. The number of cases treated in this way is now over one hundred, the supply of serum being sufficient for all cases which come, and the mortality is very much reduced. The chief drawback, I think, is the fact that the cases come late. The statement of the parents is not usually accurate, and children who are said to have been sick one or two or three days present every appearance of having been sick much longer, with the throat full of membrane, nasal discharge, perhaps hemorrhagic, and the glands swollen; in fact with all the signs of a longer period of sepsis. The throat contains various germs (streptococci, staphylococci); if the infection is a mixed one, it is not amenable to treatment by this serum; and the number of deaths is greater than if the children were brought during the earlier days. That seems to be the chief reason, in fact, why the serum cannot be regarded thus far as strictly a specific for all cases.

The complications I have observed also. It seems that the skin complications are of little consequence, but the most troublesome one which has fallen under my observation has been the arthritic pain which Dr. Withington referred to, a rheumatoid condition of the joints of the lower limbs, which in two cases I have seen lasting from two to three weeks. Exactly what its nature may be is not clear, whether a septic complication or a neuritis. The pain is in the soft parts as well as in the joints, but in the cases I have seen it has disappeared without any permanent ill effect, so that it seems now as if we can be fairly confident that this remedy is safe from any serious drawbacks.

DR. WITHINGTON: I have not the tabulation of cases from which the report was drawn up, but three-fourths of all the injections were with the New York serum, and I think it is safe to say that a still larger proportion of the cases in which the injection was made early and which did not do well, were made from that serum.

DR. MORSE: I have also tested a specimen of Gibier's antitoxin according to the method given by Kossel in the *Deutsche medicinische Wochenschrift* of October 25, 1895, and in the specimen tested there were only two and a half immunization units to the cubic centimetre; that is, if, as Ehrlich and Kossel claim, 500 immunization units are necessary for the treatment, you have got to give 200 c. c. of the specimen which I tested.

I also want to speak of the diagnosis of mixed infection by the bacteriological examination of the throat. It seems to me it is not fair to say that because you find streptococci in the throat that the case is necessarily one of mixed infection. The streptococcus is such a common bacterium in the throat normally that you are not justified in making the diagnosis of mixed infection because you find it there.

I wish to speak briefly of a case which I saw in

[1] See page 249 of the Journal.

consultation with Dr. Thayer of Wenham. The patient, a girl sixteen years old, was given 50 c. c. of Gibier's antitoxin in divided doses. As far as the diphtheria went she did remarkably well. She had an urticaria on the fifth day which lasted two days, and on the eighth day after the first injection she had a sudden rise of temperature, accompanied with very severe abdominal pains which lasted two or three days. Of course, it is possible that this was due to constipation or stimulation, or perhaps to overfeeding. On the eleventh day, after she had recovered from this attack, she had a sudden rise of temperature to 104°, with very severe pains in the arms, especially localized in the shoulders and elbows, but no swelling in the joints and no redness. The pain lasted forty-eight hours; the temperature fell to normal; and she had no paralysis and made a normal convalescence.

Dr. F. H. Williams: I have been very much interested in Dr. Withington's cases, and certainly can agree with him in the wonderfully prompt results which follow the use of antitoxin when it is used early in the disease. He spoke of the difficulty of making the diagnosis by means of the bacterial test. It seems to me that difficulty is encountered more often in laryngeal cases; it seems as if the bacilli were more apt to be either overlooked or perhaps not so easy to be obtained on the swab.

As regards Behring's solution and urticaria, I think we can hardly expect to be free from cases of urticaria in diphtheria by using Behring's solution. I have used only Behring's or Aronson's solution, and unfortunately have had urticaria from both of the German makes of antitoxin.

As regards the arthritic pains and the discomfort, I have had three cases in which this was quite severe, and one case in which disturbance of this character was serious for something like six weeks, the patients suffering a great deal, and one or two presenting the appearance of periostitis. There seemed to be a tenosynovitis, a good deal of swelling of the joints and a great deal of pain, and it seemed to me that that might have been due to the antitoxin.

As regards its use as a preventative of diphtheria, it seems to me that in adults who can be constantly under observation it is at present hardly worth while to use it. In one of the cases, an adult in whom I used the solution — perhaps not enough — I used only one cubic centimetre of Aronson's solution, which is as much as he recommended, but not a very large amount — the patient on the sixth or seventh day developed a diphtheria which promised to be a severe one; but how severe it would have been I do not know, because I gave ten cubic centimetres of the Behring solution on the second day, and she did very well.

I should like to ask Dr. Withington if he knows what make of serum was used in the fatal cases where the injection was made early. I think he mentioned several cases where, although the antitoxin was used early in the disease, the patients died.

I have here a syringe which seems to me rather a simple one for injecting antitoxin. I do not know whether that is the one Dr. Withington refers to. It seems to me this syringe is useful for other purposes. They are easily sterilized and comparatively inexpensive. The ordinary antitoxin syringe costs four or five dollars. I suppose this one would cost a dollar and a half.

Dr. Osgood: I should like to ask what the indication is for the quantity of antoxin necessary in a given case, whether it be the condition of the patient, the degree of dyspnea, amount of membrane, or age of the disease. For instance, in one *résumé* of cases, five cubic centimetres were injected for all ages from three to twenty-four years, and in a case which came under my notice twenty-five were injected. What is the indication for the quantity to be injected?

Dr. Withington: A primary indication is the lateness of the case rather than the size of the patient. Cases that come late certainly require more than those that come within twenty-four hours, and if you assume that the quantity, for example, necessary for the immunization of a child from two to five years old is three cubic centimetres a proportional dose for the same child within the first twenty-four hours after the development of the disease would be fifteen to twenty cubic centimetres, and a person who first came under treatment later in the disease would have a correspondingly larger dose. I think the dose is an indefinite quantity at the best because the specimens even from the same manufacturer, vary. I am told by Dr. Ernst that Gibier has told him that successive products from his establishment will require to be used in smaller and smaller doses. But our first invoice was marked one to eighty thousand; and, instead of giving us a stronger solution, they dropped on the next lot to a solution that was marked one to fifty thousand. It is probable from what Dr. Morse ascertained as to the actual strength in immunization units of this particular make that the dose has got to be larger than was at first supposed in order to accomplish anything. Until the immunization of the animals from which the serum is derived is carried to a greater degree than has been done, the dose has got to be rather an uncomfortably large one in order to produce the desired effect.

Dr. V. Y. Bowditch: I feel some hesitation in speaking of my experience with antitoxin because I have been only ten days on duty, and this is my first experience in the infectious wards, but the results thus far, as I have observed them and from what I read and hear, certainly seem to me encouraging, to say the least, for the use of antitoxin. Since I went on duty 26 new cases of diphtheria by the bacteriological test have entered. Of these, four have died, two being collapsed on entrance and dying the same day; one case required intubation and tracheotomy, and another case showed labored breathing and nasal discharge. According to the records, there has not been extension of the membrane in any one case, a possible exception being made in one in whom the symptoms were rather septic in character. In this one there was only a slight amount of membrane on each side of the uvula, which grew less after the first injection of antitoxin, and he was getting better even with an intercurrent attack of erysipelas of the face (from which he recovered remarkably quickly), when he showed a slight extension of reddening upon the soft palate, and membrane again appeared which has again grown thinner after another dose of the antitoxin. All the other cases are apparently doing very well, with one exception, a child who has been fighting his food and treatment since he came in.

In regard to the immunizing doses; two of the nurses under my care received immunizing doses about three weeks ago. I am inclined to think the dose was small in both cases, although I could not get precise data from either patient. One of them has already been

discharged after four days' stay in the ward, the bacillus having disappeared entirely and the membrane also. She is back again at work, not on my advice, however. In two other nurses also there was no membrane this morning after a stay of three or four days.

As to what Dr. Withington has said in regard to watching the children after the membrane has disappeared, I think it a very important fact, because just after my taking up the work it was rather disheartening to see three children who had been septic cases and had done remarkably well, suddenly, while sitting up and playing with their toys, develop symptoms of collapse and die. It is, of course, possible that these children would have died under any circumstances; but with our knowledge of the depressing effect of the diphtheritic poison upon the heart, the importance of absolute rest and quiet in severe cases, even after the most acute symptoms have passed, is made evident.

As to the appearance of urticaria, when I first came on duty there were several cases of urticaria, and one case of skin disease resembling the eruption often seen after taking aromatic medicines. It disappeared entirely the next day.

As to nephritis, we have but one case, and that developed scarlet fever.

DR. H. W. CUSHING: I should like to ask if there is danger from dyspnea by sudden loosening of the membrane.

DR. WITHINGTON: I think the gentlemen from the surgical side had the feeling that there might be an exfoliation of the membrane in the larynx which it would be difficult to expel if the tube was *in situ*, and the practice was to remove the tube a little earlier in the antitoxin-treated patients in order that its presence might not embarrass the throwing off of the membrane which the remedy would tend to produce; but that any actual dyspnea did occur from the throwing off of the membrane I am not aware.

DR. FOLSOM: I have seen little of the use of antitoxin, but I have followed the literature of the subject. The gentlemen who have seen the *Medicinische Wochenschrift* of Berlin, are aware that almost every number has something on this subject. After each meeting of the leading medical society there is usually a very long discussion, sometimes occupying several pages of that very large sheet. I have no doubt that there has been very little ill result reported so far, and it seems to me quite probable that it is quite true that the ill results are very small. From some 1,500 cases that have been carefully tabulated now, there is no question but it is safe to say that the statements by certain physicians that there is a greater proportion of nephritis with antitoxin than without it is entirely untrue. I am inclined to think that a great deal of stress should be laid upon the purity of the serum as well as the strength, and the New York Board of Health is clearly wise in cautioning all people against using any serum excepting from reputed sources. If the serum is three-fourths the strength it is reported to be, that is of little consequence because whoever uses it can find out that fact; but if it contains any impurity there is a source of a great danger. I do not know that there has been caution enough used in the country generally in regard to that point, but we can get antitoxin from the best sources hereafter. I do not think we are in a position to say what the mortality is in the use of antitoxin as compared with other methods of treatment. Of course, just as soon as any community knows that there is a valuable remedy in the hospitals which is not widely available outside of the hospitals, they will send their patients much more readily, and a larger number of mild cases will be in the hospital than heretofore. In the Paris and German hospitals and here, previous to the use of antitoxin, only the severe cases were sent to the hospital. In Germany a very much larger proportion of the mild cases have been sent to the hospitals. In regard to Paris, I do not know whether it has been so.

Many of the gentlemen will remember that a little over twenty years ago we had a very severe ontbreak of diphtheria which lasted two or three years, which extended over New England, much more severe than anything we have had since. Then a mortality of 24 per cent. of average cases as they occurred in the community was not uncommon. There were exceptional epidemics — one in Williamstown in this State, and some in the small towns in Vermont; and perhaps half-a-dozen small epidemics in which the disease was very virulent — one in Conway, in the region of Deerfield, in which the mortality was 75 per cent.; some died in twenty-four hours, some before any membrane could be seen anywhere. Leaving out those exceptional cases, 24 per cent. was an average mortality that was very commonly got in a number of towns. In Gloucester, which then had a population of 16,000, I went personally to every physician and got the name of every patient he treated and the locality of the city, to investigate with regard to the condition of drainage, etc.; and the total mortality in a very large number of cases there was less than 24 per cent, so that twenty-four per cent. probably is not an exceptionally good average to get for diphtheria in all sorts of cases. If the degree of severity of the cases that come to the hospital is still very much higher than of the cases in the community, the average mortality they are getting is a small one, and probably that is the case; but we are not in a position to say definitely in regard to that, and to say how far the reduced mortality is due to the antitoxin, and how far it is due to the fact of mild cases coming in. The statement is made frequently that antitoxin is still in the hospital stage, and various physicians state that the hospital is the only place where it should be used, because the hospital is a place for experiment. It does not seem to me that is a fair statement with the statistics which have been got from 2,000 cases, and when such a conservative man as Virchow admits that there is no evidence of any harm from antitoxin, it seems to me its use is justifiable in all cases.

DR. WITHINGTON: In regard to the percentage of recoveries quoted, of course 24 per cent. in an average of epidemics is a fair mortality for non-hospital patients. I suppose most of us expect that more than three-fourths of our patients in private practice will get well; but the patients in hospitals are ill-nourished and ill-fed children whose likelihood of doing well is less than that of the average child among the better-to-do, and there is not much doubt that the patients sent into the hospital are those who are more ill than the average. The poorer classes keep their children as long as they dare, and then send them to the hospital. The hospital mortalities have been about 50 per cent. for a number of years, and it is with that figure that we ought to make our comparisons rather than with the mortality which has prevailed in the country districts and in non-hospital patients.

## THREE CASES OF SPONTANEOUS HEMOPHILIA IN BROTHERS.

DR. JUDSON DALAND reported at the Philadelphia County Medical Society on January 9th, a case of hemophilia in a boy thirteen years of age, living in Pennsylvania at a height of 1,800 feet. The first symptom noticed was a profuse petechial eruption, which followed an attack of cholera infantum at the age of eight months. At the age of five years he began to have attacks of arthritis, which occurred on an average every two months from the fifth to the thirteenth year. Soon after the fifth year the arthritis was so severe that anchylosis ensued, necessitating the use of crutches until the ninth year, when relief was obtained from Swedish movements and massage. Between the ages of five and thirteen he had about fifty hemorrhages from the various mucous membranes, but no attacks of purpura. The attacks of hemorrhage were usually preceded by grinding of the teeth and flushing of the face, so they could generally be predicted.

Most of the hemorrhages were nasal; but on two occasions hematuria followed trauma of the renal region, and once hematemesis followed a blow on the abdomen. Later the boy accidentally bit his tongue, free hemorrhage ensuing, which lasted seven days. The nasal hemorrhage was only controlled by the application of ice to the nape of the neck and bridge of the nose, after many remedies had been tried, and large quantities of blood had been lost, so that the physician in charge thought death was imminent.

For the injury to the tongue Monsell's solution was first used, which caused a cessation of the bleeding for a short time; but soon the coagulum was loosened by the oozing of blood and saliva, so that the hemorrhage was more violent than at first, owing to the destruction of the tissue produced by the remedy. Efforts to check the hemorrhage from the use of intense cold produced by an ether spray proved valueless, as the spray could not be continued for a sufficient length of time, owing to the danger of ether narcosis and the repeated attacks of vomiting excited by the anesthetic. Compression by means of forceps was attempted, but owing to the site of the injury, which was on the side of the tongue, about two inches from the tip, it was extremely difficult to properly apply the forceps for any length of time without exciting gagging and vomiting. Ice was applied for five minutes, until the wound was partially frozen; then it was removed for a similar time, and subsequently reapplied. This was continued for twelve hours, after which the hemorrhage ceased. At that time he showed all the evidence of extreme anemia and caused his physician to think that death was imminent. Fluid extract of ergot was given in thirty-drop doses every three hours.

Dr. Daland saw the case, in consultation, for a second attack of hemorrhage from the tongue, which had been bitten during a choreiform attack. Numerous internal remedies had been tried by the attending physician, Dr. W. Duffield Robinson; but the hemorrhage had lasted six days. On the seventh day the hemorrhage decreased in quantity, ice having been applied every five minutes from six A. M. till noon. The boy showed the effects of the loss of a large quantity of blood, the heart-beats numbering 130 per minute, and the pulse at the wrist only seventy. Microscopic examination of the blood showed an enormous number of very small microcytes, many of which were mere points. There were a few macrocytes and a moderate increase in the number of leucocytes. There were no parasites nor distorted red blood-cells, and crenation and rouleauxing were normal. The blood for this examination, which was obtained at the end of a protracted hemorrhage extending over a week, showed a decidedly greater tendency to clot than on any former occasion. The Thoma-Zeiss hemocytometer showed 3,775,000 or 75.5 per cent., and Fleischl's hemometer showed 62 per cent. of hemoglobin.

The next day an examination showed well-marked evidence of quantitative and qualitative anemia, no hemic murmurs were audible, although especially searched for; the blood from the prick of the finger showed a normal tendency to clot, and the hemorrhage, which had recurred, instantly ceased when Dr. Robinson made a local application of a four-per-cent. solution of cocaine. The stomach was more retentive, and there were evidences of beginning convalescence.

The condition of the blood gradually improved, and an examination made two weeks later gave the following results: The blood emerged from the puncture freely, much more so than from a healthy individual. It was of a good color and coagulated slowly. Microscopically the blood presented a normal appearance, with the exception that there were rather more large red-corpuscles than are ordinarily seen. The microcytes had entirely disappeared. The color of the red cells was somewhat paler than normal. The Fleischl hemometer showed 70 per cent. of hemoglobin and the hematokrit showed 84 per cent. of red cells. There was no leucocytosis.

At this time the finger was accidentally cut, and hemorrhage continued for thirty minutes despite the application of ice. When a four-per-cent. solution of cocaine was employed, the bleeding was checked immediately, and did not recur.

The family history showed no hemophilia on either the father's or mother's side as far back as the fourth generation. Of their five children, however, the second at three and a half years developed hydrocephalus, and suffered from frequent severe and uncontrollable hemorrhages from the nose, of which he finally died. The third child showed no evidences of hemophilia, but died of malignant scarlet fever at two years of age. The fourth child had severe hemorrhage when he began cutting teeth, and at the eruption of the molars he bled to death.

The occurrence of these three cases in brothers, and the fact that no hereditary tendency to the affection could be traced, makes Dr. Daland's cases a peculiarly interesting contribution to our knowledge of the subject.

## CONGRESSIONAL IGNORANCE AND BUFFOONERY RESPECTING ANTITOXIN.

DURING the closing hours of the last Congress of blessed memory, a discussion arose on a bill to admit antitoxin free of duty. The chief opponent of the bill was Mr. Ray, a Republican, representing the twenty-sixth district of New York. He frankly avowed that the subject was one about which he knew nothing. We quote from the *Congressional Record:* "I do not know what antitoxin is, where it is made, what it is used for, nor whether it is animal, vegetable, or mineral, and I have inquired of a great many members of this House, but fail to find one here who has the slightest idea what this new discovery is, or what it is composed of. If it is a good thing, the owner of the patent or secret ought to come into the United States and establish an antitoxin factory here and give us an American industry; and for the purpose of building up such an industry, if its production be an industry in the United States, I oppose the bill."

Such ignorance on the part of men who are not supposed to be, but who ought to be and are not abreast of all the great questions of the day, including public hygiene, is not as astounding as it is lamentable. But Mr. Ray was not alone in not knowing what antitoxin is. His colleague, Mr. Van Voorhis, wanted to know whether the horse was not the raw material of antitoxin, and whether under the bill horses would not come in free. Mr. Henderson, of Iowa, who owned to the possession of "a stack of literature on the subject," added to his fame as a humorist by this lucid description of the antitoxin process: "They vaccinate the horse with diphtheria. Then they put him on to (*sic*) a very high grade of feeding, according to a formula which has been established, and they feed him up until his mane and tail are in the proper relations to each other, and then they bleed him; and this blood is the antitoxin." This gentleman, says the Boston *Herald*, was fully impressed with the idea that the preparation of antitoxin involved setting to work the machinery of torture on the horse, and in his most serious vein he declared that Congress should not commit itself to this animal-torturing business until they knew something about it.

Here is a fitting mission for the *Medical Record* and New York *Medical Journal* to look after the Congressmen from that State. A "whole stack of literature" consisting of excerpts from those journals' publications on antitoxin, should be at once forwarded to Messrs. Ray and Van Voorhis, who have brought this disgrace upon their State.

We would suggest that the Chicago *Sanitary News* should do the same by Mr. Henderson. Here is a new educational field open for all these journals, unless perchance they feel that it would be casting the pearls of knowledge into the mire of demagogical unworthiness.

## MEDICAL NOTES.

DR. ROSWELL PARK, of Buffalo, has recently been elected President of the Medical Society of the State of New York.

A YELLOW FEVER CONGRESS. — It is proposed to hold a congress on yellow fever during the Cotton States and International Exposition at Atlanta. The plan proposed is that the leading physicians of the city invite the leading physicians of the South Atlantic and Gulf cities, with a view of securing concert of action on quarantine measures and methods of dealing with the disease.

CHOLERA PRECAUTIONS. — Owing to the reappearance of Asiatic cholera in the suburbs of Constantinople, the Direzione della Pubblica Sanita of Italy has increased the stringency of its regulations requiring the medical visitation and disinfection of all vessels coming from the Black Sea, from the colonial French ports, from those of Russia and of Roumania on the Danube, from the Sea of Marmora, from the Ægean and from the North African littoral (excluding Tripolitania) and from Brazil. The Argentine government has formally recognized the existence of cholera in the Confederacy.

### BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, March 13, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 52, scarlet fever 31, measles 88, typhoid fever 9.

POISONING BY ILLUMINATING-GAS. — The cases of poisoning by illuminating-gas in Boston continue to be very numerous.

HEARING ON THE STATE CARE OF CHILDREN. — On March 11th, the Committee on Charitable Institutions of the Massachusetts Legislature gave a hearing to the advocates of the establishment of a separate

board for the care of children now under the charge of the State Board of Lunacy and Charity. Some people who have given the subject attention and are interested in it are of the opinion that the children, about 2,000 in number, who are now under the care of the State Board of Lunacy and Charity, would be better cared for if separated from the other wards of the State and placed under the charge of a separate board.

Insurance of Children's Lives.— A hearing is in progress, before the Insurance Committee of the Massachusetts Legislature on a bill to prohibit insurance companies from writing policies upon the lives of children less than ten years old.

Proposed Legislation in Favor of the Keeley Cure: There is a petition to the Massachusetts Legislature which will probably be referred to a committee hearing, to the effect that the Massachusetts Hospital for Dipsomaniacs at Foxboro be compelled to employ the so-called Keeley cure in the treatment of its cases.

A Protest against the Massachusetts Medical Registration Law. — Certain individuals are seeking to have amendments introduced in regard to the Massachusetts registration law, and those who desire to minimize or obstruct the operation of the law appear to think that their object would be furthered if the hearing on the amendments proposed were held before the Joint Committee on the Judiciary, instead of the Committee on Public Health.

Mr. W. B. McVey, professor of chemistry at the College of Physicians and Surgeons, has been elected a Fellow of the Chemical Society of London, Eng., in recognition of services rendered to the advancement of science during the trial of the late Dr. Meyer.

The Samuel Winslow Surgery. — Colonel Samuel Winslow, of Worcester, has presented the Worcester City Hospital with $10,000 for the construction and equipment of an operating department, to be called the "Samuel Winslow Surgery," in memory of his father, who was Mayor of Worcester from 1887 to 1890.

Compulsory Vaccination at Yale. — Owing to the occurrence of three cases of small-pox at Yale University, compulsory vaccination of all students of the university who cannot show satisfactory proofs of having been vaccinated within two years has been ordered by the faculty.

Bequests for Portland Charities. — The will of the late Ira Farrington, of Portland, Me., gives sums varying from $2,000 to $40,000 to certain named public charities. Of the residuary estate, the two-thirds part goes to the Maine Eye and Ear Infirmary at Portland, while the remaining third is devised to the Public Library.

Against the "Christian Scientists." — The following is the full text of the measure now before the New Hampshire Legislature to govern and regulate fraudulent medical practice and the so-called Christian science or faith cure:

Section 1.— No person within the limits of this State shall treat, attempt to heal or cure any other person or persons by the so-called Christian science or faith cures.

Sect. 2.— If any person shall treat, attempt to heal or cure, or claim or pretend to heal or cure any other person or persons by either of said methods and shall directly or indirectly accept or receive any money or other thing in payment for or on account of such services, or directly or indirectly accept or receive any gift or reward therefor in any form, such persons so offending against the provisions of this act by so accepting or receiving such money, gift, reward, or other thing shall be fined a sum not exceeding three hundred ($300) dollars for each and every offence, and half of such amount to be given to the complainant, the other half to the State.

Sect. 3.— This act shall take effect upon its passage.

## NEW YORK.

A New Census.—The mayor has ordered a census of the city to be taken by the Police Board. The books required for the purpose which will be printed at the office of the *City Record*, will be ready March 20th, and it is thought that this census, which will take about two weeks to complete, will be commenced March 25th. This action has been taken at the request of the Board of Health, in order to complete the official records of the latter and enable it to fix the exact percentage of mortality in the city.

Transfer of Dependent Insane. — It is announced from Albany that the Board for the establishment of State Insane Asylum Districts has reported to the State Commission on Lunacy on the request of the King's County authorities, that the State take charge of the dependent insane of that county and also possession of their care. The Board approves of the proposal that the State shall lease the Brooklyn Asylum property at Flatbush until it can transfer the inmates elsewhere. As to the St. Johnland property, which the county authorities desire to sell to the State for $500,000, the Board expresses the opinion that much money has been wasted upon it and that several of the buildings are practically worthless, while others are very imperfect. Aside from these objections, the St. Johnland property has been found to be suitable for the location of a State hospital for the insane. The price asked, $500,000, is declared to be excessive, and the Board urgently recommends that steps be taken by the legislature to fix an equitable price by negotiation and compromise.

Death of Dr. Matthew D. Field. — Dr. Matthew D. Field died March 8th, of renal and cardiac disease, at the age of forty-two. He was a son of the late Jonathan Field, who was a brother of Cyrus W. Field, David Dudley Field, and Judge Stephen Field of the United States Supreme Court. He was born in July, 1853, in Nashville, Tenn., although the permanent home of the family was at Williamstown, Mass. After being graduated at Williams College he studied medicine in New York, under Dr. Joseph E. Winter, and was graduated from Bellevue Hospital Medical College in 1879. After serving as interne at Bellevue Hospital for eighteen months, he became assistant to Dr. Stephen Smith. In 1882 Dr. Field was appointed one of the examiners in lunacy of the Department of Charities and Correction, and also

visiting physician to Bellevue Hospital; and in 1883 he was made chief surgeon of the Manhattan Elevated Railway Company. Both of these positions he held at the time of his death. He was the author of numerous articles on nervous and mental diseases, and for the last fifteen years has frequently appeared as an expert witness in lunacy cases. He married ten years ago his cousin, Miss Lucy Atwater, who, with two children, survives him.

DEATH OF DR. BERNARD E. VAUGHN.—Dr. Bernard E. Vaughn, who was an assistant surgeon to the New York Cancer Hospital, died on March 5th. He was a native of Worcester, Mass., and was graduated from the College of Physicians and Surgeons, New York, in 1887. He was a member of the house staff of St. Luke's Hospital from 1887 to 1889.

DEATH OF DR. DUBOIS.— Dr. Robert Ogden Dubois died March 9th, in the thirty-sixth year of his age. He was a graduate of the Yale Medical School in 1881, but had practised in New York for a number of years.

DEATH OF DR. AZARIAH D. NEWELL.—Dr. Azariah D. Newell, one of the best-known physicians in New Jersey, died at his home in New Brunswick on March 9th, after a short illness. He won special distinction during an epidemic of cholera many years ago. Dr. Newell early became interested in cattle breeding, and was among the first in this country to import Jersey cattle. He was of an inventive turn of mind, and a means of conveying the life line which he devised was adopted by the government and was used until the introduction of the Lyle gun.

## Miscellany.

### THE CARE OF THE SICK AND WOUNDED IN THE JAPANESE ARMY.

CHIEF SURGEON ISHIGURO has published in the *Yomiuri* an open letter to Japanese families, members of which are now in the army, which is summarized in the *Japan Weekly Mail*. A list of clothing furnished the soldiers for protection against the intense winter cold includes cotton-flannel under-garments, great-coats of woollen cloth, blankets, gloves, head-coverings of thick fur, great-coats with fur collars, flannel shirts, knitted woollen drawers, under-garments made of paper and floss silk, thick leather gloves, and an additional blanket. A large piece of fur has also been given to each soldier. Socks lined with flannel, straw foot-gear, and heavy boots have also been lately sent for both soldiers and coolies. The regular rations of rice and meat when in camp, and rice, indian corn, and pickled plums when on the march, are increased by liberal portions of fowl, pork or beef when booty is abundant.

When the enemy is to be charged at close quarters, the soldiers strip themselves of all extra clothing so as to ensure freedom of motion, and are then obliged to stand in the snow in their ordinary winter suits. On the other hand, soldiers who were the first to arrive at the enemy's quarters in Fenghwan, Chiulien, Port Arthur, etc., found fur garments and boots of great value, which they now wear.

"As to the treatment of the wounded and diseased, it is highly satisfactory to find from the returns that lately reached headquarters how comparatively small is the number of wounded and killed on our side since the beginning of the campaign. It is also reassuring to learn that the ratio of mortality among the wounded who were brought under the care of surgeons was only four per cent. The number of deaths from sickness is rather large, but it is not to be wondered at when we remember how prevalent epidemics such as dysentery, typhus, and so forth were in Korea, and what hardships the Japanese suffered owing to change of climate and of diet. It is fortunate that owing to the resemblance more or less of food and customs among the allied races of Japan, China and Korea, our soldiers are less liable to suffer than Europeans or Americans would be under existing circumstances. The mortality among the sick was also small, only about 2.9 per cent. The total aggregate of military medical attendants in the army is 1,350, of whom 380 are surgeons and chemists, and the rest male nurses. The Red Cross Society has 138 practitioners and nurses in the army, besides a far greater number who attend the wounded and the sick at the various barrack hospitals in Japan. The medical attention in the field is thus as perfect as it can well be, but as the treatment given at home is necessarily better, I have enjoined the Medical Corps in the army to send the wounded and sick back to Japan with all possible speed. When a patient has been sufficiently restored to health in Hiroshima to be moved, he is at once conveyed to a military hospital near his home, as he will there enjoy greater facilities for seeing his family and friends.

"The progress that has been made in medicine in general and military surgery in particular, in Japan, is remarkable. In the Satsuma Civil War the mortality among the wounded was 170.5 per 1,000, whereas in the present campaign it has only been 27.2 per 1,000. A short account of the Hiroshima Barrack Hospital may be interesting. The hospital is directly controlled by Dr. Sato Susumu, and under him there are 56 surgeons and dispensers and 501 nurses. Besides these there are 20 practitioners and dispensers and 153 lady nurses from the Red Cross Society. Among the latter we find Viscountesses Kabayama and Niire, and other distinguished ladies indefatigably engaged in tending the wounded and sick, together with other nurses of humbler origin. No outsider can have an idea of the care that is taken of a patient seriously ill or wounded, be he an officer or a coolie. He is generally tended by two nurses, and the treatment he receives even surpasses that given to a patient of high rank at home. The public is gratefully cognizant of the assiduity of the court in relieving the pain of the sick and wounded and providing comforts for them. The emperor frequently sends messengers to the hospital, with grants of money to the patients, and causes the military bands to visit them and play for their pleasure. The empress-dowager, the empress, and the crown prince are equally solicitous, and the former have made bandages with their own hands to be given to the patients who, however, regard them as too precious for use and hang them on their bedsteads as mementoes of the imperial benevolence.

"The hospital is visited by princes of the blood and their wives and other distinguished personages. The Chief Abbot of the Higashi Hongwan Temple and other high priests, both Buddhist and Shinto, read prayers with any patient whose case is dangerous. The contributions sent to the hospital from almost every part of the empire are almost innumerable. Bandages are, of course, the article most needed, yet such is the supply incessantly sent by well-wishers that the hospital has not had to buy a single one. Light literature contributed by patriotic people for the use of the patients already fills one warehouse. It will thus be seen that the lot of those who receive wounds or fall ill in the discharge of their duties is not hard."

The letter closes with kind injunctions to the families of those away at the seat of war to await the return of their heroes with their stories of glorious deeds achieved by themselves and their comrades.

## DUJARDIN-BEAUMETZ.

Among the French representatives of clinical medicine, no name has been more prominently before the profession during the past ten or twelve years than that of Dujardin-Beaumetz. This has been due to his contributions to medicine and the activity and zeal which he has manifested in forwarding advances in therapeutics by the critical testing in his hospital and private practice, of new remedies and methods, and the published results of those labors. He was popular as a lecturer and as a writer, and his principal works have been translated into nearly all the languages of Europe. Some eight translated volumes of his writings have been published in this country.

The "Leçons de Clinique Thérapeutique," in three volumes, has gone through eight French editions, and is a fine, lucid exposition of the most approved methods of treating the ordinary diseases. The aim of the writer was to be *practical*, and therefore just enough consideration was given to etiology, diagnosis, pathology, etc., to obtain useful hints as to treatment.

"The New Medications" has also passed through numerous editions, and contains a critical appreciation of new methods, such as lavage and gavage, nerve stretching; new remedies, such as acetanilid, antipyrin, phenacetin, exalgin, thallin, kaisin, convallaria and sulphonal.

The "Dictionnaire de Thérapeutique" (Therapeutic Dictionary) is published in four large quarto volumes and contains full consideration of almost everything of recognized utility in the treatment of disease.

Two volumes — one on Acute, the other on Chronic Alcohol-Poisoning are characterized by much original research, containing the details and results of numerous experiments extending through a series of years. An early treatise on Acute Myelitis was long regarded as an authority. Books on Hygienic Therapeutics, on Alimentary Hygiene, on Prophylactic Hygiene, etc., have appeared during the last few years and have been largely reproduced in medical journals in this country.

Dujardin-Beaumetz began his medical studies in 1853 in Paris. He became interne of the hospitals in 1857 under Velpeau and *chef de clinique* under Behier. He was three times Lauréat of the Faculty, then Lauréat of the Hospitals, and finally Lauréat of the Institute, obtaining the prize Montyon for his researches on the alcohols. He was received as doctor of medicine in 1862. He was long physician-in-chief to St. Antoine Hospital, afterwards to Cochin. His clinical lectures at both these hospitals attracted to him a large number of pupils. At Cochin he founded and equipped two large laboratories — the one for the teaching of therapeutics, the other of bacteriology, from both of which much good work has emanated.

He was a member of the Academy of Medicine, founded, and had since been President of the Société de Médecine et de Chirurgie Pratique, also of the Société de Thérapeutique. He was long officially connected with the Council of Hygiene and Salubrity of the Seine, of which he was a prominent member, devoting himself with zeal to all questions affecting the health of Paris, and especially epidemics. In 1884, and more recently in 1892, during the cholera epidemic, he rendered important service to the prefecture of police and the citizens in the effective arrangements which he organized for fighting the epidemic. In 1893 the French government, in appreciation of his services, conferred on him the Cross of the Commander of the Legion of Honor.

He was for many years editor-in-chief of the *Bulletin Général de Thérapeutique*.

It is the same old story, of attempting to do too much work, and taking too little rest and recreation. Dujardin-Beaumetz has for several years been a sufferer from hepatic troubles, and a little more than a year ago underwent the operation of cholecystenterostomy for complete occlusion of the choledochus. The operation undoubtedly prolonged his life, but he none the less eventually succumbed to hepatic infection as the sequel. He died at the age of sixty-one.

# Correspondence.

## A REMINISCENCE OF DR. HOLMES.

Boston, March 7, 1895.

Mr. Editor: — An excellent paper on "Microscopical Reminiscences," by Dr. Palmer E. Cole, published in the New York *Medical Journal* of February 23d, contains many pleasant recollections of Dr. Oliver Wendell Holmes and pays a well-deserved tribute to his great interest in the microscope, and his ingenious invention of various useful adjustments to it in those early days of its use by the medical profession. He also quotes a passage from his last letter to him, in which he says:

"My most successful contrivance was a stereoscope of a very simple pattern, which had a great run, and has remained popular, I think, to the present time."

It is well, I think, to remind your readers that this little invention, the hand-stereoscope, is one of Dr. Holmes's contrivances, as I dare say many of them, of the younger generation of doctors, are not aware of the fact. I myself have found it a very great convenience.

Dr. Cole's paper tempts me to give you a reminiscence of my own, which fully illustrates Dr. Holmes's *bonhommie* and at the same time his honest self-appreciation.

In my early student days in the Tremont Street Medical School, after a recitation in anatomy to Dr. Holmes, at which I happened not to be present, he sang to the class a new song of his own composition — probably one of his humorous medical productions, but of this I am not quite sure. Two days after, while he and I were engaged together in the dissecting-room, I casually remarked, "I greatly regret not being present at the last recitation in anatomy." "Why?" he asked. "Because I lost the song you were so kind as to sing to the students." After a moment's pause, with his head turned down a little towards one shoulder, and a peculiar compression of the lips — an attitude and expression of the mouth which all his old friends will remember, he said abruptly, "Would you like to hear it?" "Why, of course, doctor, I should," was my reply. "Well, I'll sing it to you," was his immediate response. So he laid down his scalpel and forceps, and standing facing me, with the poor relic of humanity on the table between us, he began, and went through the whole of it, with as much enthusiasm as if he were singing to a thousand people. After the prolonged applause of his audience of one had subsided, he said, "Do you like it?" "Why, of course, doctor," said I, "no one could bear it without liking it." "Well," said he, "it *is* good. *No one but a fool would pretend he doesn't know when he has done a good thing.*"

Very truly yours,

S. L. Abbot, M.D.

## METEOROLOGICAL RECORD,

For the week ending March 2d, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer | Thermometer. | | | Relative humidity. | | | Direction of wind. | | Velocity of wind. | | We'th'r. * | | Rainfall in inches. |

| Newton . . . | 28,837 | 6 | 1 | — | 33.33 | — | — | — |
| Gloucester . . | 27,293 | — | — | — | — | — | — | — |
| Taunton . . . | 26,954 | 12 | 2 | — | — | — | — | — |
| Waltham . . . | 22,058 | 11 | 4 | 9.09 | 36.36 | — | 9.09 | — |
| Quincy . . . | 19,642 | 8 | 3 | — | 25.00 | — | — | — |
| Pittsfield . . | 18,802 | 5 | 5 | 40.00 | 80.00 | — | 20.00 | — |
| Everett . . . | 16,585 | 8 | 2 | — | 25.00 | — | — | — |
| Northampton . | 16,331 | 5 | 2 | — | — | — | — | — |
| Newburyport . | 14,073 | 13 | 0 | — | 30.76 | — | — | — |
| Amesbury . . | 10,920 | — | — | — | — | — | — | — |

Deaths reported 3,487: under five years of age 1,073; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 338, acute lung diseases 812, consumption 392, diphtheria and croup 136, diarrheal diseases 48, scarlet fever 48, typhoid fever 44, whooping-cough 18, measles 17, erysipelas 10, cerebro-spinal meningitis 8, malarial fever 8, small-pox (New York) 1.

From typhoid fever Philadelphia 24, New York and Pittsburg 3 each, Brooklyn, Boston, Somerville and Lawrence 1 each. From whooping-cough New York 7, Brooklyn 4, Philadelphia 3, Worcester 2, Lowell and Northampton 1 each. From measles New York 15, Philadelphia and Brooklyn 1 each. From erysipelas New York 3, Brooklyn and Boston 2 each, Salem, Pittsfield and Marlborough 1 each. From cerebro-spinal meningitis Lawrence 4, New York 2, Boston and Washington 1 each. From malarial fever Cleveland 3, New York and Cincinnati 2 each, Brooklyn 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530, for the week ending February 23d, the death-rate was 29.6. Deaths reported 6,014: acute diseases of the respiratory organs (London) 1,119, whooping-cough 94, measles 70, diphtheria 55, diarrhœa 43, scarlet fever 33, fever 20, small-pox (London and Derby 1 each) 2.

The death-rates ranged from 17.4 in Gateshead to 46.1 in Liverpool; Birmingham 21.8, Bradford 28.3, Croydon 24.5, Hull 20.5, Leicester 19.9, London 34.0, Manchester 26.6, Newcastle-on-Tyne 21.7, Nottingham 35.2, Portsmouth 25.1, Sheffield 23.1, Sunderland 22.0, Wolverhampton 30.4.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 9, 1895.

F. W. RICHARDS, assistant surgeon, detached from Naval Laboratory and Department of Instruction and to the U. S. S. "Minnesota."

JAMES STOUGHTON, assistant surgeon, detached from the U. S. S. "Minnesota" and to the Puget Sound Naval Station.

## SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.— A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday evening, March 18th, at 8 o'clock.

Dr. Wm. A. Brooks, Jr., will present a paper on "The Educational Aspects of Physical Training." Discussion by Drs. H. P. Bowditch and Dr. E. M. Hartwell.

Dr. J. E. Goldthwait will read a paper entitled "A Report of Cases of Metatarsalgia Treated by Correcting the Transverse Arch of the Foot." The following gentlemen have been asked to take part in the discussion: Drs. E. H. Bradford, R. W. Lovett and J. Dane.

JAMES G. MUMFORD, M.D., *Secretary*.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday evening, March 20th, at 8 o'clock.

Papers: Dr. Richard Hogner; "Intravenous Medicated Injections According to Prof. Guido Baccelli's Method."

Dr. Edw. O. Otis: "The Treatment of Advanced (Hopeless) Cases of Phthisis."

JOHN L. AMES, M.D., *Secretary*.

## RECENT DEATH.

D. HACK TUKE, M.D., F.R.C.P., LL.D., the author of well-known works on mental diseases, died in London on March 8th, aged sixty-eight. Dr. Tuke was lecturer on mental diseases at the York School of Medicine and editor of the *Journal of Mental Science*. In 1881 he was elected president of the Medico-Psychological Association of Great Britain. His essays on psychological medicine, insanity and kindred topics have been valuable contributions to the subjects of which they treat. He was the editor of a Dictionary of Psychological Medicine, for which he wrote several essays.

## BOOKS AND PAMPHLETS RECEIVED.

Observations on the Action of Chloroform on the Functions of the Human Brain and Spinal Cord, as witnessed in Extensive Injuries of the Cranium and Brain. By Bedford Brown, M.D., Alexandria, Va. Reprint. 1894.

Twentieth Century Practice; An International Encyclopedia of Modern Medical Science by leading authorities of Europe and America. Edited by Thomas L. Stedman, M.D., New York City. In twenty volumes. Vol. I. Diseases of Uropoietic System. New York: William Wood & Co. 1895.

A Manual of Diseases of the Ear for the use of Students and Practitioners of Medicine. By Albert H. Buck, M.D., Clinical Professor of Diseases of the Ear, College of Physicians and Surgeons, Columbia College, New York; Consulting Aural Surgeon, New York Eye and Ear Infirmary and the Presbyterian Hospital. Second revised edition. New York: William Wood & Co. 1895.

Materia Medica and Therapeutics for Physicians and Students. By John B. Biddle, M.D., Late Professor of Materia Medica and General Therapeutics in the Jefferson Medical College, Philadelphia. Thirteenth edition, revised, rearranged and enlarged, with special reference to Therapeutics, Toxicology, the Physiological Action of Medicines and containing all the preparations and remedies described in the U. S. Pharmacopœia of 1890, to which this work has been made to conform. By Clement Biddle, M.D., Medical Corps, U. S. Navy. With numerous illustrations. Philadelphia: P. Blakiston, Son & Co. 1895.

## CLINICAL FEATURES AND TREATMENT OF EXTERNAL PILES.[1]

BY WALTER J. OTIS, M.D.,
*Surgeon to Department for Diseases of the Rectum, Boston Dispensary.*

ALTHOUGH external piles may be regarded as of no serious import, a study of the numerous cases coming under my observation convinces me that sufficient attention has not been devoted to the significance of their various phases. In a previous paper read before this Society, I considered somewhat at length their etiology and pathology, and suggested a classification based upon the nature of the abnormal processes to be recognized as the cause of their existence. At this time I beg to offer the following observations as a conclusion to the subject, asking your attention for a brief consideration of the clinical features and treatment of these swellings and vascular tumors that are at times the cause of much discomfort and real suffering. The fact is perhaps not generally appreciated that this affection affords a practical illustration of the relation between cause and effect, inasmuch as each form of external pile is the expression of a definite abnormal process which either is taking place, or has taken place, and so plainly indicates its own history that it is possible for the experienced eye to read it almost at a glance. Take, for example, the cutaneous variety of external pile, which I classify as either *redundant*, *hyperplastic*, or *hypertrophic*. The name *redundant* indicates that its distinctive feature is a superabundance, or redundancy of the circum-anal integument, brought about by the stretching it receives from the subjacent varicose external hemorrhoidal veins when they are fully distended, as during defecation. The term *hyperplastic* indicates that the pendulous cutaneous tag associated with an abrasion, fissure, or ulceration at the anal verge, is the result of an inflammatory hyperplasia. In like manner the term *hypertrophic* indicates that the swollen, thickened, radiating anal folds, associated with an eczematous inflammation, are the result of an inflammatory, or irritative hypertrophy.

The site of external piles is confined to the region of the radiating folds of the circum-anal integument. Inasmuch as the pleating of the integument is due to the firm tonic contraction of the internal sphincter, these folds radiate in all directions from just within its lower ring-like border. From this central point they pass over the lower portion of the internal surface of the external sphincter and its lower border to disappear in the contiguous skin. For it must be remembered that the lower border of the internal sphincter is subcutaneous, and that the external sphincter partially overlaps the internal. Under no circumstances are external piles to be regarded as internal piles that have been permanently crowded down and forced outside the internal sphincter. "Certainly it often happens that internal piles of long standing become habitually extruded beyond the sphincter, and can be seen surrounding the anal outlet. Nevertheless, they are still internal piles in the clinical nomenclature, since they originate within the bowel, their protrusion being merely accidental." (Cripps.) There should be no difficulty in distinguishing between external and prolapsed internal piles; because the external pile being covered with skin will have the color of skin, and will be dry with no tendency to bleed, the internal pile, on the other hand, being covered with mucous membrane will have the appearance of mucous membrane — more or less altered to be sure, especially in cases of long standing; but with this exception it will be moist, of a deep red color, with a history of bleeding, soft to the touch, with a velvety or granular surface.

External venous piles are readily distinguished from the cutaneous by their unmistakeable sanguineous nature. Some difficulty, however, may be occasionally experienced in recognizing the thrombotic pile, by reason of the complications with which it is liable to be surrounded.

The existence of a varicose condition of the external hemorrhoidal veins can probably be demonstrated on every adult. Indeed, a varicosity of these veins is of so common an occurrence that it can scarcely be called pathological, and no cognizance need be taken of it; but when repeated and excessive venous engorgement in the varicosities has produced a degree of enlargement sufficient to have caused a permanent stretching of the external anal integument, then we have to do with a pathological condition, constituting the form of external pile implied by the term *varicose*.

The *varicose pile* is seen to best advantage when in a state of venous engorgement, the turgidity and dark-blue color, together with the fact that it can be emptied by pressure, are very characteristic, and demonstrate its sanguineous nature. Its presence, however, may be surmised even when the pressure causing its engorgement is not in force, by the fact that the external skin covering the varices has been so overstretched that it cannot assume its normal shape, but will be seen hanging about the anus in numerous loose, redundant folds. That is to say, the presence of a redundant cutaneous pile is a sure indication of a varix directly underlying it. There are no symptoms connected with this form of pile aside from the mere physical ones. As a varicosity of the external hemorrhoidal plexus is always associated with and secondary to a similar condition of the internal plexus, all *treatment* of the external varicose pile must be directed to the removal of the cause of the varicosity of the internal plexus. Practically the great majority of these cases will be found in those individuals who have been subject to internal piles for a considerable length of time, and in whom the frequent prolapse of the internal tumors has produced a laxity of the internal sphincter, thus allowing a backward flow of portal blood from veins destitute of valves, and deprived of the support that a healthy sphincter affords. Hence these cases must be regarded as intimately connected with internal piles and treated like them. It is evident, therefore, that any local treatment applied to the external varicose pile, to be of any lasting benefit, must apply as well to the varicose condition of the internal hemorrhoidal veins. The tonic effect to be derived from the daily application of cold water appears to have this double effect, and can be very conveniently applied at the time of the morning bath by repeated splashing up against the anus, or by a specially arranged anal douche.

The essential element in the production of the *thrombotic pile* is a thrombosis in one or more of the dilated veins of the external plexus. I have never seen a case of thrombotic pile in which the lesion appeared to be a hematoma resulting from rupture of one

[1] Read before the Boston Society for Medical Improvement, December 17, 1894.

of these veins. It seems to me that an undue amount of stress has been put upon straining at stool as a cause of this pile. The preconceived idea that the thrombotic pile is a hematoma resulting from rupture of a vein presupposes excessive straining at stool, causing an increased blood-tension with sudden rupture of the vein at some weak point. Whereas, I have often observed in these cases that the call of nature at the customary time was put off to a more convenient one, and that when the movement took place the pain and soreness experienced was due to the tumor already formed, though not discovered by the patient until the close of the act. This rapidity of formation is one of the chief characteristics of the thrombotic pile. Another characteristic of this pile is its livid and bluish color, not at all like that of an extravasation, but rather such as might be transmitted from a thrombus, its intensity depending upon the thickness of the tissue covering the thromboseed vein. The closer the pile is to the lower border of the internal sphincter, the more painful and annoying it is — acting in this instance like a foreign body — the lower end of the rectum being in a continual state of unrest in its attempts to eject it. Even the external sphincter will partake of this spasmodic unrest and give the tumor an occasional squeeze, thus adding greatly to the pain. Standing, walking and sitting are alike equally painful, and the pain will be aggravated by coughing or sneezing. More or less edema of the cellular tissue about the vein accompanies the thrombosis; this will be most marked in those cases in which there is a redundancy of the anal integument. I cannot subscribe to the claim of most writers that the thrombotic pile terminates in the formation of a cutaneous pile. It is only when incision has been employed in its treatment or after suppuration has taken place that a cutaneous tag is liable to form, as in these events the conditions favoring the formation of an hyperplastic pile will be present.

In the *treatment* of this pile some relief will be obtained from the use of cooling anodyne applications, as the dilute liquor plumbi subacetatis, or lead and opium wash, or Pond's Extract, but the greatest amount of relief will be experienced from incision of the vein and the removal of the thrombus.

In the *redundant cutaneous pile* the normal pleating of the anal integument into compact radiating folds is replaced, in whole, or in part, by abnormal soft, loose, pendulous folds arranged about the anus like a tuft. By placing the patient in a position that will favor hemorrhoidal engorgement, and requesting him to strain, the necessity of such an arrangement of the integument will be made manifest by the skin being rounded out, and put on the stretch from the distention of the subjacent varicose veins, at the same time the natural color of the skin will change to a livid dusky blue, thus proving the existence of a varicose condition of the external hemorrhoidal plexus, and at the same time demonstrating the manner in which the redundant pile is produced. As with the external varicose pile, there are no symptoms connected with this form of pile aside from the mere physical one of a superabundance of circum-anal integument. Accordingly, from a hygienic standpoint, extra care will be required on the part of the patient to keep the part clean by the daily use of soap and water. In many persons the failure to realize the need of proper ablutions of the anus, and its consequent neglect, is the cause of many an attack of erythema intertrigo, or even a more troublesome eczematous inflammation. The redundant pile is always associated with and a symptom of internal piles of long standing, and when such cases of internal piles have become prolapsed and strangulated, there results an edema of the external redundant pile, so that the condition present will be prolapsed internal piles surrounded by an edematous swelling of the external redundant pile, and between the two will be noticed the *ano-rectal groove*. It often happens in such cases that this external swelling is considered as a part of the prolapsed internal tissue and its removal by operation advised, whereas, it is only an external evidence that such a condition is present, and all treatment should be directed to the tissue just above the ano-rectal groove, leaving the part below the groove, which is external tissue, to take care of itself.

The *hyperplastic pile* is always inflammatory in its origin, the inflammation, in this instance, resulting in a localized hyperplasia of skin and subcutaneous connective tissue in a region covered with a loose and distensible integument. The peculiar tag-like shape of this pile is due to the limited space in which it forms, being flattened laterally in the cleft between the nates. It varies in size from a small bean to a large almond. When it occurs at the anterior or the posterior margin of the anus it is very apt to assume a crescentic shape, and in the concavity of the crescent, which is directed upward, will be found the ulceration that is responsible for its presence. In an acute state the hyperplastic pile has a pinkish-red color, is very sensitive, is more or less edematous, is firm in its texture, and very much indurated. As I have already remarked, this form of pile is pathognomonic of an abrasion, fissure, or ulceration at its base, and as might be inferred, defecation is apt to be a painful and much dreaded procedure. After the healing of the ulceration at its base and with the subsidence of the acute symptoms, the hyperplastic pile will be somewhat smaller and less indurated owing to the disappearance of the edema, and the general appearance of the pile will depend upon whether the hyperplasia of skin or subcutaneous connective tissue predominates. The *treatment* of this affection to be efficacious should be fourfold: (1) to render the stools semi-liquid, (2) the protection of the ulcer during defecation, (3) the local treatment of the ulcer, (4) the removal of the pile.

To render the stools semi-liquid, it will be necessary to regulate the diet, and to administer some laxative.

To protect the ulcer during the passage of feces, I have the patient use an ointment of boracic acid (two drachms in one ounce vaseline), to be applied with the finger immediately before stool.

The treatment of the ulcer should be carried out daily by the surgeon; the first requisite for the successful application of remedies to an ulcer situated just within the margin of the anus, being the exposure of the ulcer; in a large majority of cases this cannot be done without the aid of a small-sized speculum. The passage of a small speculum under these circumstances, if introduced slowly and gently, is by no means as painful as one might imagine. After the ulcer has been exposed, it will be necessary to touch it for the first few days with nitrate of silver to get it in an active granulating state, then blow upon its surface some dry powder, as iodoform, aristol, or europhen, for the purpose of hastening cicatrization;

lastly, place directly over the ulcer a small pledget of cotton saturated with the same powder. This will keep the ulcer flat and prevent the rolling in of its edges, and at the same time will exert a certain amount of pressure upon the granulations. In this way nearly all ulcers and fissures of the anus can be cured without resorting to forcible dilatation, or division of the sphincter ani. The hyperplastic pile, as a rule, is the only form of cutaneous pile that will require excision. This will be best accomplished by using toothed scissors which have the advantage of cutting without slipping. The pain of this operation can be mitigated by the injection of a two-per-cent.— or even weaker — solution of cocaine into the base of the pile.

By the term *hypertrophic pile*, I designate the swollen and thickened condition of the anal folds that is apt to be associated with an eczematous inflammation in this region. Some exception may be taken to my inventing a special name for this condition, and considering it as a separate variety of cutaneous pile. Inasmuch as such hypertrophies do result from an eczematous inflammation, I see no objection to giving this condition a place in the clinical nomenclature, and at the same time conceding some foundation for the popular term of "itching piles." The changes to be observed in the circum-anal integument resulting from an eczematous inflammation, will, of course, depend upon the length of time that the irritation has existed, as well as the co-existence of either of the other forms of cutaneous pile. These changes may result in giving the folds a mere thickened, or swollen appearance, or they may be increased in depth as well, causing them to be more or less pendulous; in either event the condition is one of an hypertrophy of the integument involving the entire length of the radiating folds. The principal symptoms connected with this disease are itching and moisture. The attempts on the part of the patient to relieve the itching by scratching produces excoriations, and the moisture from exudation gives to the part a whitish and macerated appearance.

The *treatment* of the hypertrophic pile should be directed solely to treating the anal eczema. The patient should be instructed to resist any inclination to scratch, and the unconscious scratching during sleep should be prevented by tying the hands with a bandage in such a manner as to check any attempt at reaching the anus, while not preventing free movements about the upper part of the body. Without going into an elaborate enumeration of the various modes of treating this most distressing and intractable affection, I will merely mention what I have found to be the most useful, namely, that recommended by Dr. White, consisting in the application of black-wash and oxide-of-zinc ointment. The wash should be applied morning and night, and from ten to fifteen minutes should be occupied in sopping the wash on the part affected, and gently rubbing it into the furrows between the folds as well as on their free borders. After the wash has been allowed to dry, the ointment should be rubbed on in a similar manner. This mode of treatment has been so satisfactory that it has become with me a matter of routine in dispensary and private cases. A not infrequent cause of anal eczema is the presence of oxyurides in the rectum, and when these thread-like worms descend to the anal margin they produce by their wriggling movements a most intolerable form of itching, and the scratching and rubbing of the sufferer brings about an eczematous inflammation that will in time result in an hypertrophy of the radiating anal folds. So in every case of anal eczema the possible presence of oxyurides as its cause must be considered. An anal eczema may in certain persons be a symptom of gout, and in such cases, without the dietetic and medicinal treatment of that condition, no local applications will avail.

It must be remembered that not in every case have we to do with a single one of these types; combinations, in point of fact, are frequent. The study of the pathological varieties will enable the practitioner to analyze each complication, and to recognize the appropriate therapeutic agents suitable for the case in hand.

## A REPORT ON THE BACTERIOLOGICAL INVESTIGATIONS OF AUTOPSIES.[1]

BY J. H. WRIGHT, M.D.,
*Assistant in Pathology, Harvard Medical School;*
AND WM. R. STOKES, M.D.,
*Resident Assistant Pathologist, Boston City Hospital.*

In this paper we report the results of the bacteriological study of a large number of autopsies which have been performed at the Boston City Hospital and elsewhere, during a period of about two years prior to January 1, 1895.

This work has been carried on under the direction of Prof. W. T. Councilman, both in the pathological laboratory of the hospital and in the Sears pathological laboratory of the Harvard Medical School.

### METHODS OF STUDY.

As a rule, bacteriological examinations have been made from the various organs in every case which came to autopsy, the lung, liver, spleen, kidney and blood of the heart being usually examined. In most cases culture methods only have been used to determine the presence and character of the bacteria in the organs, but in a few instances direct examinations by cover-slip preparations have been employed for this purpose, where this mode of examination has seemed to be adequate.

The culture medium used almost exclusively has been the coagulated blood-serum mixture of Löffler, prepared in tubes in the form of "slants." This medium is prepared by a modification, originated by Dr. F. B. Mallory, of the method generally followed, so that large quantities of it can be readily made up in a short time. The special points in this modified method consist in firmly coagulating the Löffler blood-serum mixture (one part one-per-cent. grape-sugar bouillon and three parts beef blood-serum) in the ordinary dry air sterilizer at 80° to 90° C., in the form of slant tubes, and then sterilizing it in the steam sterilizer during three successive days, as in the case of ordinary culture media.

The main difficulty to contend with is the formation of cavities and bubbles in the medium by too great or too rapid heating, so that the smooth surface of the "slant" is destroyed. This can be avoided, however, by securing a thorough and firm coagulation before placing the tubes in the steam sterilizer. Care should also be taken, in the coagulation by dry heat, not to

[1] This paper will appear in the Boston City Hospital Reports, Sixth Series.

allow the temperature to get above 90° C., or the same formation of cavities may take place. The culture-medium thus prepared is opaque and of a creamy or brownish-white color, resembling in consistency coagulated egg albumin, and presents a smooth, almost perpendicular surface in the tube, upon which there is abundant space for the development of colonies.

The blood-serum used for this medium need not be collected with any special precautions to avoid contamination, and the amount of red blood-corpuscles in it is of little or no importance. The firm coagulation to which this mixture of blood-serum and bouillon is subjected does not seem to impair its nutritive qualities, as might be supposed, for one of us (Wright) has isolated the bacillus tuberculosis upon it directly from tubercular lesions, both in human and in experimental tuberculosis, a fact which is an excellent proof of its efficiency for the cultivation of bacteria.

A further proof of its great value as a culture medium is afforded by the fact that the micrococcus lanceolatus (pneumococcus) and the streptococcus grow upon it much better and more readily than upon ordinary solid media.

The method of examination of organs by cultures consists in smearing a small amount of the tissue or blood to be examined, over the smooth surface of the culture medium in a tube, by means of a stiff, flattened platinum wire, under the usual precautions, and then placing the culture in the incubator for development. After twenty-four hours the colonies which may have grown out upon the nutritive surface are examined and their character determined.

If the organ is suspected of containing large numbers of bacteria, a second tube may be inoculated from the first one by touching the sterilized platinum wire to the infected surface of the first tube, and then rubbing the infected wire thoroughly over the surface of the second. Since usually only a comparatively few bacteria will be carried over by the platinum wire and distributed over the surface of the media in the second tube, it will be found that in this tube the colonies afterwards developing will be rarely so numerous as to be confluent. If desirable, a third tube may be similarly inoculated from the second, but this is rarely necessary; and, as a rule, one tube is sufficient.

The use of this coagulated blood-serum has greatly simplified the technique of the bacteriological examination of pathological material. It possesses so many advantages over the media usually employed that we have long abandoned the use of any other form of culture at autopsies. These advantages are:—

(1) The fact that the micrococcus lanceolatus and the streptococcus grow on it much better and much more quickly than on ordinary media, such as agar-agar, while the bacillus diphtheriæ grows on it fully as well and quite as characteristically as on the blood-serum medium sterilized fractionally at low temperature, which costs so much labor to prepare.

(2) The ease with which the identification of the bacteria concerned in acute infections can be made; the microscopical examination of the original cultures made at the autopsy being in nearly all cases alone sufficient to establish the identity of the infecting organism, if this is considered in connection with the naked eye appearances of the colonies. For when cultivated on this medium the colonies of the pathogenic bacteria which are ordinarily met with in human pathology present much more characteristic appearances than when grown on agar-agar, so that to a great extent the diagnosis of the bacteria present may be made by microscopic examination alone. Moreover, in cases of poly-infection, or infection with two or more species of bacteria, the estimation of the comparative numbers of the different species is greatly facilitated by the fact that all of the colonies are on the surface, where they can assume their characteristic form, and not, as in agar-plate cultures, for instance, also in the depths of the medium, where their development is impeded, and such an estimation often difficult. We have been able repeatedly to identify with certainty three species of bacteria in a single tube and to form a clear estimate of the relative number of each. The cultural peculiarities of the species above mentioned, when grown on this medium are described elsewhere.

(3) A third advantage is the facility with which the media can be prepared as compared with the agar-agar so generally employed, the preparation of which demands great patience and considerable experience.

(4) Finally, the quickness and simplicity of the method by which cultures on this media are made at autopsies as compared with the usual methods of bacteriological examination by cultures. After a rather extensive experience in bacteriological work, we believe that the plate method and the method of Esmarch roll-tubes have no advantage over this simple method of successive "smears" when the object is to obtain discrete colonies from an infected organ or to isolate bacteria in pure culture.

Of course, when it is desired to study colonies with a low power of the microscope, the smear method is not to be used; but since in the case of the colonies of the common pathogenic bacteria such study on the usual media gives little information beyond that to be obtained by the naked eye, the simpler methods seem to answer all the requirements in pathological work, especially if blood-serum be the media employed.

## METHODS OF BACTERIOLOGICAL DIAGNOSIS.

The main object which we have placed before ourselves in this work, has been the recognition and the identification of the well-known bacteria concerned in the infectious processes which we have met with.

It is now clearly established that the important pathogenic bacteria which we have to deal with in the vast majority of cases of acute infectious disease in man are really few in number and comprise the staphylococcus pyogenes aureus, the streptococcus, the micrococcus lanceolatus, the bacillus diphtheriæ, the typhoid bacillus, and the bacillus coli communis. We have, therefore, devoted our attention towards determining the presence and identity of these species, and have not occupied ourselves with the minute study of the various unknown bacteria which have appeared in our cultures from time to time, for, either their presence could be accounted for by putrefactive processes, or there was no good evidence connecting them with the pathological conditions.

The chief characteristics of these half-dozen forms of pathogenic bacteria upon which we have based their recognition and identification are detailed in the following sections:

### THE STAPHYLOCOCCUS PYOGENES AUREUS.

This organism grows on the coagulated blood-serum in the form of golden-yellow to orange-colored, slightly elevated, shining colonies, which may in two or three

days attain a diameter of several millimetres. The great advantage in the use of this medium for the cultivation of this organism lies in the fact that the characteristic yellow color of its colonies appears immediately and not after several days, as in the case when agar-agar is used as a culture medium.

We have repeatedly recognized the presence of the staphylococcus pyogenes aureus when only a few of its colonies were present in the midst of hundreds of colonies of other bacteria, by means of this yellow color. In our work at autopsies we have not met with any other organism which produces this peculiar color, and so characteristic is it of the staphylococcus pyogenes aureus, when appearing in the cultures from an organ, that microscopic examination is hardly necessary.

The diagnosis of this organism, therefore, depends mainly upon the appearance of its colonies to the naked eye, and these considered in connection with the results of the microscopical examination to determine the morphology of the constituted organisms, are amply sufficient for positiveness. The occurrence of the other variety of the staphylococcus pyogenes, namely, the albus, has been only very exceptionally observed in our studies.

### THE STREPTOCOCCUS.

In agreement with the prevalent opinion among bacteriologists we make no distinction between the streptococcus found in erysipelas and that occurring in other conditions; but we consider that but one true species of streptococcus is concerned in human pathology, which, like the bacillus tuberculosis, is capable of inducing lesions of various forms, the form of lesion depending largely upon the tissue involved, and upon the duration of the infection.

The streptococcus grows on the coagulated blood-serum in the form of minute colonies, but more rapidly and better than upon the ordinary media. These colonies have no definite color, and when numerous are seen as fine grains or as a finely granular appearance on the surface of the medium. On microscopic examination these colonies are found to consist of cocci, in which the chain mode of proliferation may, or may not, be apparent, owing to the breaking up of the chains during the preparation of the cover-glass specimen for examination. Well-marked chains of streptococci can be usually demonstrated, however, in the fluid which is usually present at the bottom of the culture tube. This fluid constitutes essentially a bouillon culture, in which form of culture the organism finds the best conditions for chain formation, as is well known. The diagnosis of the streptococcus rests, then, upon the finding of definite chains of cocci in the culture by microscopical examination, and also upon the growth of these cocci in the form of minute colonies. The only bacterium with which the streptococcus may be confounded is the micrococcus lanceolatus.

### THE MICROCOCCUS LANCEOLATUS.

The micrococcus lanceolatus also grows in the form of minute colonies; but these are usually more moist, flatter, more shining, and generally somewhat smaller than those of the streptococcus. The appearance of the colonies is quite characteristic. On microscopical examination the colonies of the micrococcus lanceolatus are seen to consist of pairs of small oval organisms often resembling pairs of small, short, oval, lancet-shaped or conical-ended bacilli. Some variation in form and size is usually to be noted, and occasionally indications of capsule formation. In the fluid at the bottom of the culture tube longer and shorter chains may be found, which are sometimes very difficult to distinguish from chains of the streptococcus. By careful examination, however, it will commonly be found that the chain of the micrococcus lanceolatus is made up of pairs of oval organisms, while the streptococcus chain is composed of hemispherical cocci. Our diagnosis, therefore, of the micrococcus lanceolatus in cultures rests upon the minute size and the other appearances of its colonies, and the morphology of the organism itself. The pneumococcus may also be identified in the tissues by direct examination of stained preparations, by its morphology and its characteristic capsule. It may be said also that the pathogenic effect of the bacterium exhibiting the characteristics above described, has been repeatedly demonstrated on animals by the production of the characteristic septicemia after subcutaneous inoculation.

### THE BACILLUS DIPHTHERIÆ.

The morphology of this organism when cultivated upon the blood-serum, prepared by the rapid method, is quite as characteristic as when this medium, prepared by the ordinary more difficult method, is employed.

We have found this medium especially adapted for determining the presence of the bacillus in the organs of cases dead of diphtheria, because its growth on the coagulated blood-serum is so much more luxuriant and certain than upon agar-agar. In fact we consider that if agar-agar had been used instead of blood-serum in our work on diphtheria autopsies, we should have failed in many cases to have recognized the presence of the bacillus diphtheriæ, when that organism was found in very small numbers, as is most frequently the case in the viscera.

### THE TYPHOID BACILLUS.

The colonies of the typhoid bacillus on the coagulated blood-serum are round, grayish-white disks, often several millimetres in diameter, and are essentially like the colonies of the bacillus coli communis. For the identification of the typhoid bacillus we have not been satisfied with the microscopical examination of its growth on the serum, although this may give important information, if, in the fluid in the bottom of the culture tube, motile bacilli corresponding in morphology to the typhoid bacillus are seen, and the gross appearances of the colonies on the surface of the medium fulfil the requirements, but we have also applied the various tests which serve to distinguish this organism from the bacillus coli communis.

These tests are; the absence of gas-production in sugar agar or sugar gelatin cultures; the absence of any appreciable change in the litmus milk culture; the invisible growth on potato; the absence, or slight amount, of indol production in Dunham's pepton solution; active motility, and facility with which the locomotor organs, or flagella, may be stained by Löffler's method. Another distinguishing point, which we have found constant between the typhoid bacillus and the bacillus coli communis, is the less dense cloudiness of the bouillon culture of the typhoid organism.

### THE BACILLUS COLI COMMUNIS.

The colonies of this organism on the coagulated blood-serum are round, shiny, moist, and of no definite color. They grow rapidly and may obtain a diameter of several millimetres. Our experience has shown us that when colonies of this character, made up of short bacilli of a morphology corresponding to that of the bacillus coli communis, appear in a culture from an organ, they are to be regarded as colonies of that organism almost certainly, and we have generally so considered them. We have satisfied ourselves that the bacillus growing in such colonies is the bacillus coli communis, by subjecting it in numerous cases to most of the various tests for the identification of that organism. These consist in the formation of gas in sugar gelatin, sugar agar-agar, or in glycerine agar-agar suspension cultures; in the reddening, and usually the coagulation also, of litmus milk cultures; in the moist, slimy growth on potato; in the usual absence of motility; in the abundant production of indol in Dunham's pepton solution; and in the difficulty of staining the flagella by Löffler's method. The bacillus coli communis has been met with very frequently in the organs of cases of all kinds, both infectious and otherwise. In fact, so frequent has been its occurrence in our cultures that its absence rather attracts attention, and we have ceased to attach much importance to its presence, in most cases at least. From our experience we are of the opinion that the significance of the presence of this bacillus in pathological processes has been greatly overestimated.

For these reasons we have practically ignored the presence of the bacillus coli communis in reporting the results of our work. It should be understood, however, that in the vast majority of cases here reported it has been found in greater or less numbers along with the infecting bacteria in some or all of the organs.

### ACUTE LOBAR PNEUMONIA.

It is now generally believed that the micrococcus lanceolatus is the only organism which has any etiological significance in acute lobar pneumonia.

The work of a host of investigators has proven this conclusively, and has further shown that the micrococcus lanceolatus is not only concerned in the causation of the disease, but that it is frequently the infecting organism in other acute inflammatory processes, both in the lung and elsewhere. This organism was first discovered in the salivary secretion by Sternberg and Pasteur in 1880, but it was not until 1886 that Fränkel and Weichselbaum demonstrated the occurrence of the same bacterium in the hepatized lung in the majority of cases, at least, of acute lobar pneumonia.

The early history of the micrococcus lanceolatus and of the bacteriology of acute lobar pneumonia are admirably presented by Welch, in a paper published two years ago.

Welch concludes as the result of his study of the extensive literature on the subject of the bacteria concerned in acute lobar pneumonia and his own observations on fifty cases of the disease, that the micrococcus lanceolatus is undoubtedly its cause. Our own results are in harmony with this conclusion. While in a few instances we have found other pathogenic bacteria in the solidified lung, as others have done, we do not attach any significance to them, for their presence can be usually explained on the ground of secondary infection.

We have never met with the bacillus of Friedlander, which Welch considers as "probably in no way concerned in the causation of genuine acute lobar pneumonia in man."

The occurrence of the micrococcus lanceolatus in the blood and internal organs in cases of acute lobar pneumonia has not received a great deal of attention in the literature. It has been found in the circulating blood, *intra vitam*, by Belfanti in six cases, and by Boulay in two cases. Post-mortem it has been found in the blood by Pernice and Alessi in two cases, and also by Netter (one case) and Levy (one case) in intra-uterine infection of the fetus with it. In the kidneys in cases of acute lobar pneumonia the micrococcus lanceolatus has been observed by Faulhaber in 29 cases and by Fränkel and Reiche in 22 out of 26 cases. The occurrence in the spleen has been noted by Prior (five cases) and by Sée and Bordas. Welch, in his examination of ten cases, found it in the spleen in four, in the kidney in one, and in the blood of the heart in one case.

In the course of our work bacteriological examinations of the hepatized lung in acute lobar pneumonia have been made in 42 cases, and the presence of micrococcus lanceolatus demonstrated in 38. Among these 42 cases there were four cases of the unresolved or organized form of acute lobar pneumonia, in three of which the micrococcus lanceolatus was found, in one accompanied by the staphylococcus pyogenes aureus, and in another accompanied by both that organism and the streptococcus.

The staphylococcus pyogenes aureus also accompanied the micrococcus lanceolatus in one of the cases of the ordinary form. With the exception of this case and the two cases of organized pneumonia just mentioned, in all of the positive cases the micrococcus lanceolatus has been present alone or associated with the bacillus coli communis, or similar non-significant organisms. In two of the four cases in which the micrococcus lanceolatus was not found, the negative result may be ascribed to the large number of apparently unimportant bacteria which were present, and which may have prevented the development of the feebly-growing micrococcus lanceolatus.

Of the two remaining negative cases, in one the staphylococcus pyogenes aureus and bacillus coli communis were found, and in the other the streptococcus, the bacillus diphtheriæ and the staphylococcus pyogenes aureus.

In the first case there was coincident a purulent epididymitis with multiple abscesses in the kidneys, and in the second there had been empyema, thoracentesis and general infection with the streptococcus. It seems probable that the abundant growth of the various bacteria found in these two cases in the lung may have obscured the recognition of the micrococcus lanceolatus or prevented its development in the culture, if present.

As to the occurrence of the micrococcus lanceolatus in the various organs in these cases of acute lobar pneumonia, our results may be summed up as follows:

The micrococcus lanceolatus has been found in the liver in 8 out of 26 cases examined; in the spleen in 6 out of 26 cases; in the kidney in 11 out of 26 cases, and in the blood of the heart in 3 out of 11 cases. It is apparent, therefore, that there is more of a general invasion of the blood by this organism than is generally supposed.

PLEURITIDES.

The most extensive investigations of the bacteria concerned in exudative pleuritis are those of Levy, Netter, Koplick, Jakouski, Prince Ludwig Ferdinand and Prudden. The results obtained by these bacteriologists and others have shown that there is no one species of bacteria constantly associated with this condition, but that any of the common pathogenic bacteria and others may be present. From the work of Prince Ludwig Ferdinand and of Prudden, it would appear that cases in which the micrococcus lanceolatus is found have a better prognosis than others.

Of 13 cases of fibrinous pleuritis accompanying acute lobar pneumonia the micrococcus lanceolatus was found in 12, in practically pure cultures in nearly every case, the contaminating organism being usually the bacillus coli communis. In the single negative case various unknown bacteria were present. In all of four cases of purulent pleuritis coincident with acute lobar pneumonia the micrococcus lanceolatus has been present, in two cases in company with the staphylococcus pyogenes aureus. Of three additional cases of fibrinous pleuritis, not accompanying acute lobar pneumonia, the micrococcus lanceolatus was found in two (in one along with the staphylococcus pyogenes aureus) and the streptococcus in the third case.

Also, in two out of three additional cases of purulent pleuritis, not associated with acute lobar pneumonia, the micrococcus lanceolatus was present, in one case with the streptococcus, and in the other with various unknown bacteria. In the third case the staphylococcus pyogenes aureus was found (culture taken a few hours before death). This was a case of purulent broncho-pneumonia and general infection with the staphylococcus pyogenes aureus.

ACUTE PERICARDITIS.

The bacteriological examinations of the exudate in acute pericarditis recorded in the literature are not numerous.

Weichselbaum has found the micrococcus lanceolatus in several cases; Bainti the same organism in two of three cases; Steinberg in one case; and Thue in four out of five cases. Barbacci in the examination of three cases found the staphylococcus pyogenes aureus in one and the micrococcus lanceolatus in two cases, while Foureur in one case found the streptococcus.

The occurrence of other bacteria in pericarditis have also been reported by Ernst (tubercular pericarditis), and by Paviot.

In seven out of 10 cases of acute pericarditis, seven of which accompanied acute lobar pneumonia, the micrococcus lanceolatus has been present. Of the three negative cases, in two only the bacillus coli communis was found, while the other case was sterile. In one additional case of acute pericarditis in which no culture was taken from the pericardial exudate, a streptococcus septicemia was demonstrated, so that it is fair to conclude that the pericarditis was due to that organism.

It may also be mentioned that a case of hemorrhagic pericarditis after abortion was negative for specific bacteria.

PURULENT LEPTO-MENINGITIS.

The extensive literature on the subject of the bacteria associated with purulent lepto-meningitis has recently been summarized by Flexner and Barker in their interesting study of epidemic cerebro-spinal meningitis. According to these writers the micrococcus lanceolatus has been found in the great majority of the numerous cases recorded in the literature, while the streptococcus, the staphylococcus pyogenes aureus and other bacteria have been met with in but a small proportion of the cases.

This very frequent occurrence of the micrococcus lanceolatus in purulent inflammation of the pia mater has been observed in the cases examined by Flexner and Barker, as well as in those here reported.

In eight of 11 cases of purulent lepto-meningitis and in one case of the sub-acute form the micrococcus lanceolatus has been present. The staphylococcus pyogenes aureus accompanied the micrococcus lanceolatus in one of the eight cases of purulent meningitis.

Of the remaining three cases of purulent meningitis, in one the streptococcus was found and two were negative; but one of these negative cases was probably due also to a streptococcus infection proceeding from an otitis media, in the pus of which that organism was present.

Two of the micrococcus lanceolatus cases were secondary to fracture of the base of the skull, the fracture going through the petrous portion of the temporal bone, and thus, by presumably placing the brain cavity in communication with the pharynx, through the Eustachian tube, an infection-atrium for the micrococcus lanceolatus, so common an inhabitant of the throat, was provided. Acute lobar pneumonia was coincident in two of the micrococcus lanceolatus cases and in the negative case. Otitis media was also coincident in one of the same cases.

*(To be continued.)*

## HALLE AND THE AURAL CLINIC OF PROFESSOR SCHWARTZE.

BY GEORGE L. RICHARDS, M.D., BOSTON.

HAVING recently spent a semester with Prof. Hermann Schwartze at Halle, Germany, some account of his work and methods may be of interest. Halle is a manufacturing city on the river Saale in Saxony, not far from Leipsic. Outside of the university there is little of interest to Americans. The medical department is in the same inclosure with the hospital, beautifully situated on a hill away from the university proper, and with attractive grounds. Every department has its own building; and as the buildings are all new, the equipment of the medical department as a whole is as fine as any in Europe. Everything is wonderfully clean, and arranged on a thoroughly antiseptic basis, being in this respect in marked contrast with the Vienna clinics, where everything is theoretically antiseptic, but not practically so to nearly as great a degree.

There are few especially noted professors; and about the only branches foreign students can study to advantage are otology, ophthalmology and bacteriology. Behring, one of the discoverers of antitoxin, occupies the chair of hygiene, having recently succeeded Renk. Eberth, the discoverer of the bacillus of typhoid fever, teaches bacteriology; and von Hippel is professor of ophthalmology, a chair long held by von Graefe. The eye clinic is a large one, and lasts from quarter-past eight to twelve or one daily. There are usually from four to six operations. Seven thousand new out-

patient cases are yearly treated and there are seventy beds for in-patients. I saw the operation of discission of the lens for myopia of high degree several times performed, and always with good results, useful vision following the removal of the resulting cataract. Unlike Vienna, where a student can begin work almost any day, in any branch and continue as long as he pleases, paying the fees directly to the instructor, in Halle and many other German university towns every student must matriculate and arrange and pay for all courses in person at the office of the university. Private courses, as given in Vienna, are also unknown.

Matriculation is a matter of considerable red tape, and consumes much time. Foreign students must furnish a diploma from some recognized university or a certificate from some German or Austrian university. No courses can be begun or even arranged for until all matriculation formalities are finished. Then the student receives a card certifying that he is a member of the university, and from that time on is held by the same rules as all undergraduate students. Although taking only special courses and having no connection with the university proper, I was once fined five marks for failing to observe some petty ordinance of whose existence I was totally ignorant. The penalty for non-payment of the fine was confinement in the university prison for three days. The expense of living in Halle is very small, about half as much as in Vienna. It is also a good place in which to learn the German language, providing one knows something of it before, as absolutely no English will be heard.

Professor Schwartze's (clinic) occupies a portion of the same building with the eye clinic, and has some twenty-eight to thirty beds for in-patients. The out-patient clinic begins at eight A. M., and the ordinary treatment is done by assistants. Daylight is used for illumination except on very dark days. He holds a public clinic three times a week, lasting about one hour and a quarter, beginning with the examination and demonstration of cases by his students and ending with a lecture. An operation almost always follows, and students are detailed to assist. Operations are done on other days also; in fact, mastoid operations are of almost daily occurrence. It is as an operator on the mastoid that Schwartze is universally known, but before taking up that subject I will mention some points in otology, taken somewhat at random from my notes, which will illustrate the man and his methods. Everything which he does is very thoroughly done. Very complete clinical histories are taken of all house-patients, including always an examination of the nose and naso-pharynx and frequently of the fundus of the eye as well. Here, much more than in Vienna, is the intimate relation between affections of the ears, and the nose and naso-pharynx recognized, and treated accordingly. Adenoid vegetations and hypertrophied tonsils are always to be sought for, and, when found, removed. Suppuration of the middle ear cannot be healed while enlarged tonsils or adenoids are present. For the removal of adenoids, anesthesia is not used; but the antiseptic preparations are as elaborate as possible — gown, sterilized instruments and absolutely clean hands. Tonsils are removed with the Mathieu tonsillotome, and adenoids with Volkmann's sharp spoon. Any part remaining is removed with the finger-nail or Meyer's ring-knife through the nose. This method causes considerable bleeding, and did not seem to me to have any advantages over the use of a properly curved Gottstein's knife or the Lœwenberg forceps. Schwartze does not approve of removing adenoids and tonsils at the same time, in private practice. He would remove the adenoids first, and then keep the child in bed for two or three days on liquid diet and away from other children. He thinks there is some danger from catching cold and from sepsis, as he has seen one death from infection, follow the operation. If all goes well after the removal of the adenoids, the tonsils can be removed a few days later. He thinks hemorrhage after tonsillotomy is more feared than the facts warrant. This may be so, but I once saw quite a degree of hemorrhage follow the removal of adult tonsils in London, with the Mackenzie instrument. In the case of a child, if the palate is dark blue and the crying violent, there may be some danger.

Politzer's method of inflation is but seldom used; and Schwartze lays down the rule that it is never to be used for one-sided affections. Inflation is almost always done through the catheter. Instead of the usual Politzer bag the double bag of Lucae is used. This consists of two rubber bulbs connected by a short piece of tubing, the second bulb being covered with netting. At the end of the second bulb is a piece of rubber tube, and attached to this a disinfecting capsule containing absorbent cotton. From the capsule extends more tubing, and at the end there is a small quill which fits into the catheter when in position. As the apparatus is a little heavy, a hook is attached to the tubing a short distance from the disinfecting capsule, so that the whole can be suspended from the lapel of one's coat. For use, the second bag is filled from the first and then compressed with the hand. The advantages claimed for this are more uniform air-pressure and greater cleanliness. The air introduced is absolutely clean; and as all air enters the bulb from the same place and always in the same direction, there can be no sucking back into the bag or into the catheter of secretions from the Eustachian tube, naso-pharynx or nose. The diagnosis tube is always used.

Chronic purulent catarrh of the middle ear with a perforation large enough to permit the free discharge of the secretions is treated by syringing through the catheter. Should the opening in the tympanic membrane be small, it may be advisable to enlarge it. Physiological salt solution (previously boiled), or sublimate (1–10,000), is used for this purpose; carbolic solution never, as any solution of carbolic acid strong enough to do any good would cause great pain. The catheter must be absolutely in the right place, and the fluid at about body temperature. The patient is told to breathe in and then hold the breath. During the period of rest, the syringing is done. This cleans out the attic and tympanic cavity more thoroughly than any other method. The syringing is continued until the fluid comes out of the external canal free from any secretion. Syringing through the catheter, while sometimes painful, is not usually so, providing the perforation is sufficiently large to permit the free escape of the introduced fluid.

Powders are not very much used in suppurative middle-ear cases, and always in small quantity, never sufficient to prevent the free outflow of secretion.

Aural polypi are removed with the Wilde snare, and the point of origin cauterized with nitrate of silver or chromic acid. Schwartze has no faith in the alcoholic treatment for polypi, and thinks they recur because they have not been completely removed.

He is not very enthusiastic over removal of the stapes for cure of noises, vertigo, or very great deafness. He thinks the operation should only be done when noises are very troublesome, both ears affected, the patient complaining very much, and with the understanding that the expected improvement is not at all certain. The operation has the possible danger of injury to the facial nerve with resulting paralysis, owing to the near relation of the canal of the facial to the foramen ovale. He removes the stapes only through a wound made from behind. The membranous external canal is separated from its bony attachments and drawn forward with the retractor, a portion of the bony canal and attic wall is cut away and the posterior border of the tympanic membrane cut through and laid forward. The stapes is much more readily reached and foot-plate and all removed. Schwartze regards this method as preferable to operating through the canal, where there is always danger of breaking the crura and leaving the foot-plate in position. Even by this method failure to remove the foot-plate sometimes happens.

Children suffering from foreign bodies in the external canal, should, if syringing fails to remove them, be anesthetized before using forceps or any forcible attempts at extraction; and this failing after reasonable time, extraction should be done from behind. After separating and drawing forward as much as possible the membranous from the bony external canal, and the body being still firmly impacted, sufficient bone should be chiseled away to allow removal. The after-treatment consists in preventing the closing up of the external canal, and is brought about by keeping it filled with plugs of gauze until the healing is complete.

Before doing paracentesis the external canal should be made antiseptic, the cartilage scrubbed, and the nose and naso-pharynx sprayed with antiseptic solution; no anesthesia. The usual paracentesis needle is employed and the opening if necessary further dilated with a blunt-pointed knife. If there is no marked swelling to indicate the point of operation it is done in the post-inferior quadrant as here there is no danger of injuring other structures. The cut should be large enough to allow of the free escape of secretion. The catheter is to be used afterward, the nose having been previously cleaned as indicated above. The after-treatment must be thoroughly antiseptic. Fill the ear with a pledget of iodoform gauze and dress as after more severe operations, and keep the patient in bed. Paracentesis in an out-patient clinic is disapproved of unless absolutely necessary, and then only under strict antisepsis.

Schwartze regards the operation of tenotomy of the tensor tympani muscle as having only temporary results in the way of improving the hearing and lessening the noises; at times the hearing becomes worse instead of better. The method of operation is that in general use. A cut is made one millimetre behind the handle of the malleus; a suitable curved tenotome is introduced through the cut with the point in the direction of the tegmen tympani; it is then turned forward at a right angle till the tendon of the tensor is reached and with a sawing motion this latter is cut through.

Tenotomy of the stapedius may be of use when the free movement of the stapes is hindered through retraction. The operation is done with a paracentesis needle or crescent-shaped knife, and is possible only when the tendon is visible.

The operation of dividing synechiæ of the membrana tympani is not regarded as of much worth, as they tend always to re-form. In cases of perforation, with adhesion of a portion of the border to the inner wall of the tympanum, closure of the perforation never takes place.

The malleus and incus are removed for chronic suppuration in the tympanum, or in the hope of improving the hearing and removing the subjective noises. The many cases which I saw done, and the two which I myself did, were all for chronic suppuration with a large perforation and more or less destruction of the tympanic membrane. I do not know that the method differs from that in use by other operators, except that after freeing the tympanic membrane from its marginal attachment and dividing the tensor tendon the Wilde snare is used to remove the malleus. It is sometimes quite difficult to snare the end of the handle after it is severed from its attachments and possible adhesions, and has the disadvantage that in case the whole of the malleus were not absolutely free from adhesions, pulling with the snare might separate the handle from the head. The incus is removed with Ludwig's hook, being first dislocated and then brought downward and forward into the field of vision or into the external canal when it may be removed with snare or forceps. The removal of the incus is often quite difficult. It may lodge in the opening leading to the antrum or in some fissure. Sometimes removal fails with instruments, and at another time it can be syringed out. As the incus is more often carious than the malleus, it is necessary always when the malleus is removed to remove the incus also. Nothing, however, should be done in the way of operations on the external canal except under good illumination and with all bleeding stopped. One should be able to see to the deepest point. The chorda tympani nerve is sometimes injured but no evil consequence results. Facial paralysis and dizziness may appear after this operation. It usually disappears in from six to eight weeks, at latest six months, though it has lasted longer.

Healing takes place in from eight to fourteen days, and where the operation is done on account of purulent or carious conditions the results are usually good. In cases of sclerosis and when done for noises or deafness or synechiæ, Schwartze regards results as very uncertain.

Before taking up the mastoid operation I will briefly describe Stacke's method of laying bare the attic, a procedure which enters into many of Schwartze's operations. The skin cut is made in the usual manner except that the cut is carried above the ear to the fascia temporalis, and the attollens aureus muscle is cut through. All bleeding vessels are tied; the cut then extended through the periosteum to the bone, and with the periosteotome the membranous portion of the canal is separated from the bony, and the whole cartilaginous ear drawn forward with a retractor, leaving the bony external canal bare. The tympanic membrane is divided on its upper and posterior border. One now chisels away the tegmen tympani at its posterior superior angle, and so much of the adjacent bony canal as may be necessary to lay the attic bare to the antrum, frequently probing so as not to go too far in any direction, especially upwards. The bones, if not already destroyed by caries, are then seen to lie free *in situ*, and after tenotomy of the tensor, and

freeing of the incus-stapes joint, if necessary, are easily removed. With the sharp spoon preferably, or further chiselling if necessary, all carious bone in this situation can now be removed. The membranous canal, having first been slit in a direction corresponding to the long axis of the external canal, is now laid back in such a way as to cover so far as possible the bony surface previously laid open, and the original incision stitched. A drainage-tube is placed in the external canal to prevent any stenosis during healing.

The indications for the mastoid operation, as originally given by Professor Schwartze remain practically unchanged. Briefly these are:

(1) In acute primary and secondary inflammation of the mastoid, if after the use of antiphlogistic remedies, the edema and fever do not, in a few days, at most eight, disappear.

(2) In chronic inflammation with swelling, abscess formation, fistula in skin or secondary abscess in the neighborhood, even if at the time there appears to be no immediate danger to life.

(3) In chronic suppuration of the middle ear without signs of inflammation of the mastoid, as soon as any symptoms dangerous to life appear or seem at all probable, in consequence of pus-retention or the formation of cholesteatomata.

(4) In cases of otherwise incurable neuralgia of the mastoid.

(5) As a prophylactic measure in incurable fetid middle-ear inflammation, without inflammatory symptoms in the mastoid and without signs of pus-retention, as soon as it is demonstrated that the seat of pus-formation is not limited to the cavity of the tympanum.

Schwartze regards the operation as practically devoid of danger when properly done; even in those cases where no pus is found in the mastoid cells, but only inflammatory swelling of the pneumatic cells, the results seem oftentimes to be as good as in the cases where pus is found. On the other hand delaying to do the operation often costs the life of the patient. He thinks many lives are lost through too long delay or because conditions demanding operation are not recognized and acted upon.

Cholesteatomata in the middle ear and accessory cavities indicate themselves by the presence of symptoms of cerebral irritation, one-sided headache, dizziness, etc. In these cases the indication is always for the largest possible opening into the antrum from without. Should cholesteatomata be present without dangerous symptoms, the removal of the epidermal masses may be attempted with forceps, spoon, curette or syringing through Hartmann's canula, but healing is never brought about in this way. The moment more acute symptoms appear, as pain and fever, there is danger to life and the operation is urgently demanded.

Persistent incurable purulent discharge from the middle ear does not demand operation if limited to the tympanic cavity and its contents, and not involving the mastoid. In these cases removal of any carious parts through the external canal answers all the indications.

When the bone is much sclerosed and consequently very hard, the external signs of pus over the mastoid may be entirely absent and yet the mastoid cells much excavated and cholesteatomata or pus be present in large amount. In these cases of very thick bony wal there is frequently either a fistula in the external canal or a deficit in the posterior upper quadrant of the tympanic membrane; sometimes, though much more seldom, a large carious depression through which one can go with a probe into the mastoid.

Schwartze regards the opthalmoscopic examination of the fundus oculi as a valuable aid to diagnosis. Optic neuritis coincident with ear symptoms, in otherwise normal eyes, other causes for the eye symptoms being excluded, indicates intra-cranial complications such as increase in amount of subarachnoidal fluid, and urgently indicates operation. If the neuro-retinitis is very marked and apparently progressing, the prognosis is bad and an operation may be contraindicated. Hence the rule is laid down, though I cannot say that I saw it always carried out, that in cases of mastoid disease an ophthalmoscopic examination should be made. Advanced tuberculosis, great anemia, and albuminuria, a late stage of diabetes, and meningites may be considered as among the affections which contraindicate operation; and yet the operation may be demanded even in the presence of these.

The two principal landmarks in the operation are the linea temporalis and the spina supra meatum. The greatest care must be exercised in the region of the former in order to avoid the possibility of opening into the middle fossa of the base of the skull and injuring the dura. The spina sometimes, though rarely, fails; and the skin over the mastoid, usually thin, may be as a result of pathological processes quite thick. Before operation the hair should be cut quite short, and a sufficiently large area around the site of operation shaved and then scrubbed with soap followed with ether and sublimate.

The first incision should begin about one centimetre behind the insertion of the auricle, beginning one centimetre above the linea temporalis and following the line of insertion of the auricle, carried to the apex of the mastoid process. In cases of great edema or where the sides of the cut cannot be sufficiently separated, it may be necessary to lengthen the cut in both directions, or even to make an incision backwards at right angles, at about the level of the external canal. Following the first incision, which goes to the periosteum, sometimes to the bone, all bleeding vessels are tied until the field of operation is free from blood. With a dull periosteotome the bone is then laid bare, in front to the border of the external canal, above to the linea temporalis, below to the apex of the mastoid process, behind as far as needed; the prime essential at this stage being, to have a field for operation which is large enough and which is free from blood. The bone is now opened unless caries or perforation from pus has already made an opening and the amount and extent of the operation determined by the findings. Professor Schwartze never starts out to do any particular operation, but only to remove with the chisel and sharp curette all of the diseased bone. If to do this it becomes necessary to remove the whole posterior wall of the external canal or the outer attic wall, he always does so. If the mastoid wall is outwardly sound, then the point chosen to begin chiselling, will be that from which the antrum is easiest reached. This point is usually about five millimetres underneath the linea temporalis at about the level of the superior wall of the bony canal five to ten millimetres behind and on a level with the spina supra meatum. Normally at this point the bone shows a number of openings for nutrient foramina. The operation is to begin on the point of the mastoid only when there is

reason to think that the trouble is there, although in cases of extensive caries the whole apex may be chiselled away.

In cases of cholesteatomata the operation is very thorough. Here he removes the whole cortex over the involved area, and chisels away every bit of infected bone. As in cases of extensive general caries, with pus and granulations, throughout all the cells, the whole posterior and upper wall of the external canal is cut away, laying bare the cavity of the tympanum, and removing any portions of the small bones which are not destroyed. Before cutting away the wall between the antrum and the tympanic cavity a probe is always passed into the cavity from the antrum and the wall chiselled away over this probe as a guide. In all other cases, especially in sclerosis, it is superfluous to remove more than is necessary to make a way to the antrum. The depth of the antrum is usually twelve to eighteen millimetres. If the cortex is thickened or the whole mastoid sclerosed, as may come after long purulent processes, it is deeper. No absolute rule can be given as to how deep to go, owing to individual peculiarities. In general, it is not safe to go any deeper than the depth of the external canal or tympanic membrane, otherwise there is danger of wounding the facial nerve and labyrinth. Schwartze exercises the greatest care whenever chiselling near the Fallopian canal. Exceptionally the facial nerve is met with at the depth of eighteen millimetres; at twenty millimetres the greatest care must be observed and twenty-five millimetres never exceeded.

I did not gather anything new from Professor Schwartze as regards the pathology of cholesteatomata, but the measures he adopts to prevent recurrence are quite novel and unique. As is well known, cholesteatomata are often of very great extent, even encroaching at times on the dura. They have a great tendency to recur some months or years after removal. To prevent this Professor Schwartze makes the opening in the mastoid as large as possible, and then lays therein a flap of skin. Before doing this, however, in all operations where the bony external canal has been chiselled away, the membranous portion previously held forward with a retractor is slit on a director from its attachments to the tegmen tympani as far as the pinna, and a smaller cut then made at right angles to the first at the outer end. The two free ends of the membranous wall are next stitched to the upper and lower border of the periosteal surface of the original incision over the mastoid. This throws the external canal and the cavity made by the operation into one. A skin flap from three-fourths of an inch above to one-half of an inch in width below and parallel with but longer than the first incision over the mastoid is now dissected off behind, being left attached above. This flap is brought forward and laid in the cavity from whence the cholesteatoma was removed. The resulting bare space is left to granulate and cover with new epithelium. The transplanted flap is held in place by one stitch in front and by a wad of sterilized gauze. The wound as in all operative cases is dressed with iodoform and sterilized gauze and the dressing unchanged for seven days.

I was able to follow such a case for some weeks after the operation. The skin flap lived and became attached in its new situation and the place from whence it was removed was covered over with new skin. The cavity in the bone being entirely covered with healthy skin and granulations, there is no chance for the cholesteatoma to again form. Schwartze has now followed this plan for many years and finds that there are practically no recurrences. While there is a large cavity which always remains open behind the ear, that must be protected from the entrance of water and dust and from the cold in winter, yet these persons are able to work and become practically sound as far as the ear is concerned. I saw such a case four years after removal of a cholesteatoma with healing of the skin flap in hole. There was a little black stuff in the hole but no symptoms had appeared in the meantime.

In this connection it may be said that cosmetic effects are not considered in Germany to anywhere near the extent they are in this country, where no larger permanent hole will be left behind the ear than is absolutely necessary, and where as a general thing granulation from the bottom and final filling up and obliteration of the cavity is allowed and favored. On the other hand, in Schwartze's clinic, in cases of cholesteatomata the hole is always kept open, being touched with nitrate of silver from time to time to prevent the filling up with granulations; while in Professor Lucae's clinic in Berlin, nearly all the mastoid cases had large permanent holes behind the ear occupying the site of antrum and aditus.

The possible dangers in the operation are venous bleeding; injury to the facial nerve and semicircular canals and opening the middle fossa of the base of the skull. Venous bleeding can come from large veins in the bone which communicate with the jugular or its branches. I once saw quite a degree of hemorrhage come through the floor of the external canal from the jugular, necessitating stopping the operation, which, however, was practically completed. Injury to the latural sinus causes profuse bleeding, easily controlled by tampons of iodoform gauze. The operation, if not completed, must be postponed some eight days or so until the resulting thrombus is fully organized. No ill results follow.

Much more common than troublesome hemorrhage is injury to the facial nerve, and, moreover, not only in that portion of the Fallopian canal which is above and behind the round window and on the lateral wall of the antrum, but also farther under and outward on towards the stylomastoid foramen, a portion of the canal that shows in its course many variations. In most cases the paralysis disappears after several weeks or months. Only when the nerve is completely cut through is it complete and lasting. The paralysis may not appear until some time after the operation. It is then the result of a perineuritis extending from point of injury, caused probably by pressure from blood exudation in the canal. Whenever during an operation the region of the Fallopian canal or the round window is reached, the greatest care is exercised and an assistant told to watch for the slightest sign of involuntary swallowing so as to avoid if possible any injury to the nerve; still it sometimes happens.

Injury of the labyrinth may follow the use of the chisel as well as the drill, and death can result from purulent inflammation. Loss of hearing, dizziness, and disturbance of gait always follow injury to the labyrinth.

If by accident the dura is laid bare or even opened, no danger is likely to follow if the operation is as nearly aseptic as possible, and has no more unpleasant

results than does laying bare the lateral sinus. In fact the dura is often laid bare in operations where the caries is very extensive. One precaution must be taken, namely, that the edges of bone have no sharp points which can by any possibility injure the dura. The change of dressings should be made with great care so as to avoid any injury to the granulating surface.

Schwartze sutures the skin wound and allows it to heal by first intention only in those cases where with the exception of the antrum the bone is quite sound, or where one can be certain that every bit of diseased tissue has been removed. In all other cases the wound must be kept open until all evidences of pus in the tympanic cavity or antrum have disappeared and the whole wound has granulated at least on the bottom. The first dressing is changed only when stained through.

For instruments, chisels with straight and concave cutting edges varying from two to eight millimetres in width and eleven centimetres long; two large chisels with concave cutting edges eighteen centimetres long, and ten and eight millimetres wide are used. They are used with great care, and I never saw a false cut made. As a caution to be observed he directs that, in order not to injure the lateral sinus, the chisel should never be directed backward. The chisel must never be held at right angles to the plane of operation, but always slanting as nearly horizontal as possible. The chisel must always be directed from the linea temporalis, never towards it. The sharp curette of various sizes is very much used in exploring and removing soft bone, fungoid granulations, and cheesy pus, followed by the chisel if, as is usually the case, the curette does not completely remove the diseased tissues. Retractors of several sizes, right and left tenotomes, and incus hooks, several knives, a number of artery forceps and a mallet complete the necessary instruments. Chloroform is used for anesthesia as in most of the German clinics. With all its advantages it is dangerous, and I have several times — not only in Schwartze's but in other clinics, seen the course of an operation suddenly interrupted because the patient had ceased to breathe properly and the pulse had almost stopped. Artificial respiration is commenced, the windows opened, and when the breathing and the circulation again becomes natural the operation is resumed.

During some ten weeks attendance on Professor Schwartze's clinic I saw but one death, and that a case of tuberculous caries of both mastoids in a child of five years, after removal by operation of nearly the whole mastoid and the laying bare of a large area of the dura on each side. I do not think the operation hastened death, which occurred some three weeks after from exhaustion; the lungs were also tuberculous.

In general Schwartze's operations impress one by their thoroughness, the careful attention to every detail, the absolute antisepsis, both as regards operation and operator, the extreme care used, and the entire absence of hurry; mastoid operations lasting frequently an hour and even longer. I was there in the summer semester, and most of the operations were on account of caries or cholesteatomata, that is, chronic cases, though there were some acute mastoid cases. The wards were usually full of operative cases. As soon as convalescence after mastoid operation is established and healing well along, a metal spring one-half inch wide, provided at one end with an ear-shaped expansion and passing from one auricle over the head to the wound, is employed to hold the dressing in place.

While the basis of the preceding article consists of my notes, I have, in addition, availed myself of the section on Operations in Schwartze's "Handbuch der Ohrenheilkunde," where an exhaustive account of the present state of operative otology may be found.

## Clinical Department.

### A CASE OF PANCREATIC CYST TREATED BY DRAINAGE; RECOVERY.[1]

BY MAURICE H. RICHARDSON, M.D.,
*Surgeon to the Massachusetts General Hospital; Assistant Professor of Anatomy, Harvard Medical School.*

N. D., an Italian laborer of twenty-six, I saw at the State Almshouse on November 22, 1894, with Dr. Howard. He had always been well and strong up to his present illness. He first noticed a painless swelling in the pit of the stomach six weeks before operation. This swelling gradually grew larger, and became so painful that he could not sleep at night. There was no interference with digestion or bowels. The appetite was good. The pulse and temperature were normal, the urine contained nothing abnormal. There had been some loss of flesh. The general appearance was poor, and the face cachetic. I found a non-resonant, fluctuating tumor, as large as an adult head, in the epigastrium, a little to the left of the median line. The tumor was so large as to interfere seriously with his comfort, embarrassing respiration and distending tensely the upper half of the abdomen. I made a diagnosis of cyst of the pancreas, from the position of the tumor and from the history of the case. Immediate operation was decided upon; for though the patient's condition was not serious, it clearly indicated the necessity of interference.

A cut was made between the umbilicus and the ensiform cartilage. The stomach and transverse colon presented themselves on opening the peritoneum. The omentum having been carefully separated, the tumor was brought into view, and its contents aspirated. "The fluid was viscid and of a dirty-gray color. The reaction was alkaline, and the specific gravity 1.008. There was about one per cent. of albumin, and a considerable amount of mucin. There was a little sediment which showed an occasional fatty degenerated cell. The fluid did not emulsify fat, and had no diastatic action. It had no digestive properties." [Report of Dr. W. F. Whitney.]

About two pints of fluid were withdrawn by aspiration. The parts about the exposed portion of the tumor were then walled off with gauze, and a free opening was made by which about two quarts of fluid escaped. Exploration with the finger showed a large cavity situated in the retro-peritoneal space usually occupied by the tail of the pancreas. The bodies of the lumbar vertebræ could be felt, as well as the pulsations of the abdominal aorta. No stone could be detected.

Separation of the tumor was attempted; but, on getting into the deeper parts, the adherence to the surrounding structures was so intimate, and the blood vessels were so numerous, that no further efforts at

[1] Read before the Boston Society for Medical Improvement, December 17, 1894.

enucleation were made. The cyst wall was stitched to the abdominal wound, and a large drainage-tube was inserted. The subsequent history was marked by rapid diminution in the amount of fluid discharged. Three weeks after the operation a specimen was sent to Dr. Whitney which possessed all the characteristics of pancreatic fluid.

In the surgical treatment of pancreatic cysts the important question to be decided is between drainage and radical removal of the sac. In two previous cases reported by the writer, drainage in the manner described above proved effectual. In one [2] the discharge grew gradually less, and the wound became perfectly healed in a few months. A second [3] healed perfectly; but a year or two later the cyst reappeared, and proved fatal. A second laparotomy was performed [4] for symptoms of acute intestinal obstruction due to pressure upon the duodenum by the re-filled sac. At the autopsy a large opening was found between the cyst and the stomach. The cause of death was acute obstruction. A third case, referred to me by Dr. F. C. Shattuck,[5] though of doubtful pancreatic origin, was cured by complete extirpation of the cyst. The patient, a child of thirteen months, referred to Dr. Shattuck by Dr. Bowers of Clinton, had had a tumor in the abdomen since birth at seven months. The tumor rapidly increased in size, and embarrassed both circulation and respiration. The whole abdomen was filled by a fluctuating tumor, apparently arising from the left, supposed to be a hydronephrosis. The tumor was dissected from its attachments back of the peritoneum in the pancreatic space. There were numerous large vessels supplying it, and it was crossed by the splenic vein. The tail of the pancreas was spread out over the anterior wall of the tumor. Seven pounds of fluid were removed. Drs. Fitz and Whitney reported the tumor to be of retroperitoneal origin, and congenital. More detailed examination showed true pancreatic tissue in the cyst wall. My own observations convinced me that the pancreas was involved only by pressure from behind. The child made a good recovery, and has grown up into a very robust boy.

In this case enucleation was rapid and easy. By avoiding the splenic vein and by tying the pedicle *en masse*, no hemorrhage ensued.

In the fourth case, reported above, attempts were made to remove entirely the cyst wall. The difficulties met with early in the attempt led to its abandonment, and the usual practice among those who have operated for this condition was followed.

Recently a case has been reported [6] in which the whole cyst was successfully enucleated. That such a method is preferable, if safe, is doubtless true. Yet if the cyst is a dilatation of the canal of Wirsung, it is evident from the excessive discharges during the first few days after drainage that the digestive processes will lose permanently a large amount of pancreatic fluid by the method of total extirpation. Numerous observations show that complete healing takes place after drainage in most cases, and that the danger from this method of treatment is slight. It seems, therefore, well to follow this method generally. If the cyst can be easily separated from its attachments and thoroughly extirpated without excessive hemorrhage, it seems best to attempt such a procedure, in view of the possible re-accumulation of fluid, with its remote dangers, as in the second case cited. The attempt at enucleation should be abandoned, however, as soon as it is evident that the cyst is so thoroughly incorporated with the surrounding pancreatic tissues that it can be separated only by cutting.

In the case reported above the diminution of discharge has been rapid, and the general improvement has been marked. Nine weeks after operation I found the cavity of the cyst obliterated, nothing remaining but a sinus through which a probe could be passed nearly to the bodies of the lumbar vertebræ.

## FRACTURE OF THE HUMERUS FROM AN UNUSUAL CAUSE.[1]

BY G. H. MONKS, M.D.

A WELL-BUILT and apparently healthy man, aged twenty-seven, entered the Boston City Hospital August 8, 1894, having sustained a transverse fracture of the right humerus, just below the insertion of the deltoid. The patient had first been seen by Dr. John Gillespie of Roxbury, who recommended him for admission to the hospital.

The following is the history of the injury. The patient, C. C., and a friend of his were testing their strength of arm by that well-known method of grasping right hands, palm to palm, over a table, and while the elbows rest upon the table each tries to push his opponent's hand down. I do not know of any English name for this sport, but Hamilton says that the French call it "tourner poignet," or the game of turning wrists. The illustration shows the position taken by the contestants in this sport. The elbows should, however, perhaps be a little nearer together than is shown in the photograph, so that the forearms may be more nearly parallel.

C. C. and his opponent were both exerting considerable force, and for a time neither seemed to gain any advantage, until, finally, C. C. began to push his adversary's hand down. At this moment the adversary

[1] This paper will appear in the Boston City Hospital Medical and Surgical Reports, Sixth Series.

made a sudden effort to regain his position, using all his force, when with a snap, so loud that it could be heard all over the room, C. C.'s humerus broke, and his arm fell helpless upon the table.

As to the subsequent history of the case there is nothing noteworthy. The arm was immobilized in the usual fashion in coaptation splints, shoulder-cap, etc., and in the course of six weeks the fragments were firmly united without deformity, and soon after this the arm appeared to be as strong and useful as before the accident.

Several cases of fracture of the humerus during the carrying out of the above form of sport have been recorded, but so few are they as to justify the publication of each new case. Hamilton states that he has seen one case of the kind, and refers to six or seven others which he has found recorded. Stimson ("Treatise on Fractures") mentions the fact that Gurlt gives eleven cases of the sort. It is probable that some of Gurlt's cases are included among those mentioned by Hamilton.

The mechanism of a fracture of the humerus from the above cause is interesting. Apparently the break is occasioned mainly by a twist, or torsion of the shaft of the bone. While the muscles of the upper end of the bone are attempting to rotate the bone inward, the adversary's force (transmitted through the bones of the forearm to the lower end of the humerus) tends to rotate it outwards. The upper end of the bone is therefore forcibly rotated inwards and the lower end is rotated outwards. It is thus evident that when these two opposing forces are great enough, and the other parts do not give way, the bone must break by extreme torsion somewhere between the two extremities. This must be especially true when the fracture occurs while the forearm is flexed at a right angle on the upper arm. When, however, the shoulder is brought much nearer to the hand, as is often the case during the greatest efforts, and a fracture occurs, another element probably comes somewhat into play, and the bone breaks by a combination of torsion and outward bending. Torsion still remains, however, the principal mechanical factor in causing the break.

While the etiology of this fracture is undoubtedly muscular action, it seems to be a rather unusual form of it, and the break might be described as one due to torsion of the shaft of the humerus, caused by prolonged muscular action against resistance suddenly and unexpectedly increased.

In closing, I wish to say that careful investigation was made respecting the existence of syphilis in this case, with negative result. There was also no evidence of the presence of fragilitas ossium.

## Medical Progress.

### RECENT PROGRESS IN PATHOLOGY.

BY W. T. COUNCILMAN, M.D.

(Concluded from No. 11, p. 258.)

WOODHEAD in a lecture on the present state of our knowledge of the etiology of carcinoma, gives a critical review of the most prominent articles on the subject. He comes to the conclusion that in many of the rapidly growing carcinomas, coccidia may be present in great numbers. In others growing more slowly they are less numerous. There is no proof that these organisms are the actual cause of the disease, and it is possible that infection with the parasites is favored by weakening of the life energy of some of the epithelial cells, so that they cannot oppose the entry of the parasite into them.

Ruffer, in a number of publications, gives a study of the cell inclusions in carcinoma. In his investigations he usually used Biondi stain. Ruffer and Plimmer investigated principally the carcinoma of the breast, in which the parasites were found to be more frequent than in the same tumors originating elsewhere. They think that the parasites of other species of carcinoma present a striking similarity to those of the breast, and that they may be varieties of the same species. The more rapid the growth of the carcinoma the more abundant were the parasites. The bodies described by Ruffer as parasites have much similarity with the descriptions of other authors, particularly with Foa. They regard the structures as described by Darier and Wickham as altered epithelial cells, leucocytes, etc. Pfeiffer has also studied the parasites of carcinoma. He thinks that many cells, which have up to the present been regarded as tissue cells, should be considered as parasites. Where there was a growth of carcinoma into striated muscle, he thinks that the cells found within the muscular fibre were neither due to proliferation of the muscle cells nor were cancer cells which had entered into the muscle, but should be regarded as parasites. He assumes that the parasites at a certain stage can take on forms which are very similar to the tissue cells and which he regards as forms of zoospores. In the warm stage slow ameboid movements can be recognized in them. In sections he found nuclear figures in these supposed parasites of the same character as those found in the carcinoma cells. He thinks that the supposed small-cell infiltration of the stroma surrounding the carcinoma alveoli is due to the wandering of new zoospores in the tissue. Adamkiewitz has the same view. He thinks as Pfeiffer, that the carcinoma cell is not a cell of epithelial origin, but a parasite. He implanted small masses of carcinoma in the brain of rabbits, and found that the animal soon died, from which he concludes that the carcinoma has a specially poisonous character which is due to a toxine produced by a parasite. As is well known, he made various attempts to heal carcinomas with a material derived from them, which he called cancroidin. The animals experimented on died of meningitis and encephalitis.

Geissler and Kopstein repeated the experiments of Adamkiewitz in a careful aseptic manner, and found that pieces of tumor could be implanted in the brain without producing any results. Korotneff describes structures in the carcinoma as parasites, which are entirely different from the structures described by other authors. He distinguishes two stages of development, in one of which the parasite appears as an actively moving ameba, and in the other this has divided into secondary spores.

Numerous authors have taken a different ground as to the nature of these bodies. Malassez, who was one of the first to believe in the presence of the sporozoa in carcinoma, in a later publication takes a very reserved position. Delépine, although he thinks there is much similarity between certain forms of the supposed carcinoma parasites, and the young coccidia in the liver of rabbits, finds on the other side such great differences between them that there can be no thought

of identity. Coates thinks that many of these supposed parasitic bodies in the carcinoma may be referred to endogenous cell division. He compares the carcinoma in its development with the infectious granulation tumors, and concludes that if a parasitic organism is found in them it has nothnig to do with their etiology. He finds many features of carcinoma which are opposed to the assumption of its parasitic character. The manifold forms under which the tumor may appear would make it probable that every carcinoma must have a separate parasite, and further there remains unexplained the peculiar preference of carcinoma to develop in the later years of life. Kasin, after an investigation of about 60 carcinomas, concludes that the existence of coccidia in them cannot be proven. The structures described as coccidia he thinks may be produced by irregular divisions of the nucleus by a peculiar form of intra-cellular multiplications. Stroebe describes in the carcinoma inclusion-cells which have been regarded as parasites. He thinks there may be some possible connection between these intra-cellular bodies and the condition of the nucleus described by Klebs as hyperchromatosis. He thinks that the parasitic etiology cannot be explained in some forms of carcinoma. And from what we know of carcinoma in general it is not impossible that a parasite belonging to the class of sporozoa may be shown to be the etiological factor; but no proof has been given for such an assumption, and no proof has ever been offered that any of the supposed bodies described really have a parasitic character. Cornil thinks that enclosed leucocytes may be responsible for those structures in the cells which have been regarded as parasites. Kosinsky shows that degenerative processes can so alter the ordinary structure of the carcinoma-cell that the appearance of cellular inclusions may be given. Rebbert regards the much-discussed cell-inclusions as nothing but degenerated epithelial cells or their nuclei. The degenerations are most marked in the cells which are concerned in the formation of epithelial pearls. One cell can be completely enclosed by the surrounding cells, or a portion of one can project in the protoplasm of another and become enclosed in this. Then a section through the cell would give the appearance of a free body within the cell. These enclosed cells or portions of cells can undergo various metamorphoses which can affect both the protoplasm and the nucleus, and different pictures similar to parasitic inclusion could arise. The radiated striation at the edge of the enclosed bodies, on which so much stress has been laid by Foa and others, he thinks is probably due to the striated border of the enclosed epithelial cells. Unna describes a hyaline degeneration of the epithelial cells of the carcinoma which he thinks may give rise to the conditions described as parasites. The hyaline formation may appear as a diffuse, uniform hyaline infiltration, or as sharply circumscribed structures within the cell. The circumscribed hyaline degeneration may produce structures of the most manifold forms which may be limited to a single cell, or may affect the cells in the periphery. He describes eight different forms of this hyaline degeneration, many of which are very similar to certain animal parasites in the encapsulated condition. Klein has found that structures similar to the fuchsine staining bodies described by Russel were produced in the tissue cells in the course of different pathological processes. He thinks that the Russel bodies have the same origin as those described by Altman and which are due to cell-granulation, which have become enlarged with assimilation of fat. Raum found in eight carcinomas by using Altman's methods, the round granules described by Altman in the cell protoplasm. Ohlmacher has found in certain substances the power of precipitating saffranin from solutions, and thinks that many of the supposed parasites are simply artifacts. Similar bodies to those described in carcinoma have been found in other pathological conditions, and even in normal tissues. The Darier bodies have been found in an angio-keratoma. Unna found them in cutaneous horns, and in most of the hyper-keratoses. Peterson saw similar bodies in condylomata and in the warty growths of the glans penis. Similar bodies have been found in the normal epithelium of the cornea and in skin tuberculosis. Virchow found similar structures in normal epithelial cells and in the pearly tumors. In the Hassels bodies from the thymus of the fetus and the newly born, and in the epithelial masses enclosed in the prepuce there are structures which are similar to the supposed sporozoa described in carcinoma. Kenner has found the inclusions described in carcinoma in simple inflammatory affections of the skin.

A number of papers on the same subject were read at the Eleventh International Congress. These consisted generally in a repetition of the statements embodied in this report. Foa again described the bodies which he found enclosed in cancer cells, and which he considers as parasitic in character. These bodies consist of a central mass of protoplasm surrounded by a double-contoured membrane. The protoplasm frequently shows radiating lines extending from the centre, which give the bodies the appearance of rosettes. These segments do not separate, as is the case in the malarial organism. The central body becomes enlarged, the protoplasm atrophic, and it then divides into small masses, which may be spores. Cell-multiplication takes place around the parasites but not in the immediate vicinity of them. They are found both in the primary focus and in the most recent metastatic nodules; and in doubtful cases of carcinoma the presence of these parasites may make the diagnosis easy.

Cornil read a paper on various modifications of the nuclei and cells in cancer which have been regarded as parasites. The nuclei of the cancer cells frequently divide into a number of secondary nuclei, many of which may remain in the protoplasm, complete division of the cell not taking place. Some of these nuclei can take the most varied forms, and may give rise to the appearances which have been considered as parasites. White blood-corpuscles may also be found in and between the cells, and these may give rise to similar appearances. He does not think that theoretically there is anything against the parasitic idea of carcinoma, but up to the present all of those who have most prominently advanced this view have limited themselves to the similarity of the morphology of the supposed structures to various forms of parasites. He thinks that all of the supposed parasites are probably nothing more than modifications of cells and nuclei. Morpurgo finds the position of these bodies in the cells has some relation with the poles of the ochromatic spindle, and are found where the so-called intermediate bodies of the nuclei are found. Their sizes and shapes vary. They may be round or egg-shaped, or have the shape of a cap or crescent. He thinks it is probable that they consist of free chromatic sub-

stances which have been given off from the nucleus. The observations of Kasin and Duplay on the same subject correspond with those of Cornil. They do not think that any proof has been offered that the bodies are parasitic.

Frænkel has also studied these carcinoma bodies with a variety of stains and with different methods of preparation, and comes to the conclusion that they are intra-cellular structures of the most varied character and origin, and not parasites. Galleotti comes to the same conclusion.

In the general discussion of the subject Schrom says there are two chief questions to be considered: first, whether the objects described in the carcinoma are really parasites; and, second, if they should be proven to be such, whether there is any genetic connection between them and the carcinoma. He thinks that some of the bodies may be parasitic. Foa and Ruffer defend the parasitic view, and think that the parasitic nature can be shown by various modes of staining. Even in fresh tissues they have been able to stain the parasites by teasing the tissues in methyline blue.

A general consideration of the articles referred to here shows that the question is still undecided, but by far the weight of evidence is opposed to the parasitic idea.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

JOHN T. BOWEN, M.D., SECRETARY.

REGULAR Meeting, Monday, December 17, 1894, DR. C. F. FOLSOM in the chair.

#### PATHOLOGICAL SPECIMENS.

DR. M. H. RICHARDSON: I have here two drawings of the appendix. The first appendix was removed on Saturday from a man in whom the probable diagnosis lay between some pancreatic affection and a pylophlebitis. He had a clear history of appendicitis antedating the operation some weeks. The symptoms finally pointed to the upper abdomen. We made the incision between the ensiform cartilage and the umbilicus. Nothing whatever was found there. The appendix was, however, clearly diseased, as demonstrated by digital exploration. It was delivered through the high incision without much difficulty. The patient was immediately cured of his symptoms, and has been well ever since. The other appendix, which I removed three days ago, shows the reason why some of these cases are so rapidly fatal. The opening was so close to the cecum that it discharged fecal matter with extreme rapidity. Although the operation was done within twenty-four hours from the appearance of the initial symptom, the peritonitis was already so extensive that there was practically no hope. The man died to-day. I think this case throws much light on the etiology of these rapidly fatal cases, their fulminating course being due not so much to the nature of the poison as to the size of the hole.

This kidney shows a perforating gunshot wound for which I performed nephrectomy four days ago. The renal vessels are extensively lacerated. The ball, after tearing the renal artery and vein, passed through the substance of the kidney transversely. The course of the bullet was extremely curious and interesting. The missile entered the abdomen to the left of the median line, just above the umbilicus. It could be felt in the right lumbar region under the skin. A straight line between these points would be likely to pass through the transverse colon, the duodenum or stomach, pancreas, and right kidney. The aorta and inferior cava would also lie in its track.

Clinically there were only the signs of hemorrhage. No intestinal or gastric wound could be found even after the most thorough search. The retro-peritoneal tissues were extensively infiltrated with blood as far even as the left kidney. A tear could be felt in the right kidney.

After nephrectomy and control of the hemorrhage, it was found that the bullet had entered the left lobe of the liver, passing thence through the quadrate and right lobes to the kidney. This course is impossible in the prone position. Erect, the liver must have hung much lower, so as to bring the hole in the liver to a level corresponding with the wound of entrance. The patient died two days later. At the autopsy no peritonitis was found.

I have here another kidney, which I removed to-day. It is of great surgical interest. The patient was a boy, six or eight years of age, who came to the Massachusetts General Hospital during my service in the spring. I examined him carefully many times, and made a diagnosis of sarcoma of the kidney. Operation was advised. This was declined, and the boy left the hospital.

A few days ago he came to the Eliot Hospital, where I decided to perform nephrectomy. The tumor was very large, filling the whole left side of the abdomen and projecting beyond the median line to the right. It was irregular along the right border.

On opening the abdomen I found the descending colon lying across the tumor. The mesentery of the descending colon lay directly in front of the right half of the growth. The intestine and mesentery were separated with the greatest care from the anterior wall of the tumor. After this the kidney was delivered without much difficulty. It was necessary, however, to scoop out the softened centre of the mass, in order to make the whole small enough to be delivered through the wound in the parietes, although this incision extended from the rib to the crest of the ilium in the left linea semilunaris. After breaking up the central portion of the tumor, there was little or no difficulty in separating the rest of the growth from its capsule.

The greatest danger in the operation upon these cases is from hemorrhage. There was no difficulty in this case, however, in controlling the vessels. The tumor is soft and friable. A large portion is wanting. This was removed by breaking up the centre of the softened mass in order to deliver the whole tumor. The wound by this procedure was extensively infected by malignant cells. It was hoped that no evil result would follow, for the parts were cleansed as thoroughly as possible before closing the abdominal wound. The renal vein shows a portion of the growth projecting into the blood-current. The long duration of this growth, with its extensive and intimate attachments, makes the prognosis as to early recurrence very unfavorable.

February 13, 1895. The patient made a rapid recovery. Late in January I found a most extensive

recurrence. Some of the stitch-holes in the skin were infected. The boy died early in February. The rapid and extensive local reappearance of this disease seems to point unmistakably to an auto-infection at the time of operation.

Dr. S. J. Mixter: This is a tumor of the orbit that I removed Saturday from a woman of thirty, who had noticed that the eye had been protruding five years. The eyeball had become very much pushed out downward and forward. It was a question whether the mass was a cyst of some kind, perhaps a suppuration spreading from the frontal sinus, or a solid tumor. She had been told by one physician that it was a bony tumor of the orbit. It proved to be this soft solid, which was enucleated very easily; and when removed, the eye fell back into its normal place. The incision was made through the eyebrow. The tumor, which is the size and shape of a pullet's egg, extended well back to the sphenoidal fissure. The lachrymal gland was also removed, as it was adherent to the mass, though it proved to be free from disease. Dr. Whitney reports that the growth is an endothelioma.

Dr. W. J. Otis read a paper on

### THE CLINICAL FEATURES AND TREATMENT OF EXTERNAL PILES.[1]

Dr. S. J. Mixter: The reader has covered the ground so thoroughly that there is very little left to add. The description he has given of the anatomy of the parts is most useful, especially in cases where one has to operate on internal hemorrhoids associated with this edematous external hemorrhoidal condition which he has mentioned. It is, of course, much better to stop at this fold and not burn deeply into the skin, as is sometimes done, and in that way give the patient pain from the superficial burn.

In regard to the thrombosed pile, Dr. Otis spoke of the danger of making tabs or tags from incision. The relief is so immediate and so great that I think, if there is pain, incision is always the best treatment, as it can be so simply and easily done with the injection of a little cocaine. I find that cocaine of one-fourth per cent. is as effective as the two-per-cent. solution; and I believe some of the fatal cases of cocaine-poisoning have been from the injection of the two-per-cent. solution about the rectum going directly into the vein. So, in this region, I think it is advisable to use weak solutions.

There is one method of treating the hypertrophic or eczematous pile which I have used with great success in cases where thorough local treatment with blackwash and ointments has failed, and which has not been mentioned by the reader or any other authority on this subject, so far as I am aware: that is, excision of the redundant folds of skin. The hypertrophied radiating folds rub against each other, and are macerated with the retained secretion. By removing the most prominent of the folds by elliptical incision, and sewing up the wounds with fine silk or catgut, all the folds are flattened out, and there remains a smooth surface that in a short time becomes perfectly free from the eczematous process. In this way I have cured, not only the eczema about the anus, but also secondary eczema of the scrotum that had resisted all local applications.

As Dr. Otis has stated, one of his photographs was taken from a patient of mine who had ulcerating as well as hypertrophic piles. I removed the whole mass by dissection, and united healthy skin to healthy mucous membrane, and the patient is perfectly cured.

Dr. J. C. White: There is only one point on which I would say something, and that is with regard to this last variety of conditions described by the reader—simple eczema around the anus arising ordinarily from pure and simple pruritus, often entirely independent of any hypertrophy of the region; and it applies as well to those cases in which eczema is present from other causes. The care of the parts after stool, is, I think, one of the most important measures in the treatment of these distressing cases; and often a simple remedy will be sufficient to prevent future attacks of any severity at all, namely, the use of wetted paper at the water-closet. I always direct a certain quality to be obtained, very smooth satin-finish. Take three sheets, fold upon themselves so that it makes them square and dip them in water just before using. Take successive portions to cleanse the parts. In that way no friction is set up. Wet paper cleanses the parts thoroughly and keeps them clean until the next stool. Very often the omission of this for three or four days is sufficient to bring back the eczema. That I insist upon as of chief importance in the treatment of pruritus of these parts. Then, I think you get an advantage in having the parts smeared at night with some simple ointment like the mixture of camphorated and carbolated cosmoline, smeared on gently. With these two measures I think we get our best success in the treatment of this condition.

Dr. Richardson: I have listened to this paper with a great deal of interest, and learned very much from it as I did from the paper a year ago from Dr. Otis. We are obliged at our clinics to treat these forms of anal disease, though perhaps we have not any special experience with them except such as we gain there from observation. I was surprised to know you could cure a fissure of the anus by anything but etherization and stretching. I must say that is one of the most gratifying of surgical operations I know of, and I can see no injury from it. I think I should prefer the rapid cure to prolonged treatment, but I am glad to know it can be cured by such a method.

[1] See page 269 of the Journal.

## Recent Literature.

*Laboratory Guide for the Bacteriologist.* By Langdon Frothingham, M.D.V., Assistant in Bacteriology and Veterinary Science, Sheffield Scientific School, Yale University. Illustrated. Philadelphia: W. B. Saunders, 1895.

This book consists essentially of a collection of the more common technical methods used in the bacteriological laboratory, outlined in the simplest possible form, and is designed as a work of reference for the beginner. The directions for the preparation of the ordinary nutrient media are not the best with which we are acquainted, but are in some respects needlessly long and complicated. We are glad to note, however, that the rapid method of making blood-serum culture tubes has been included. A serious omission is the absence of any directions for the staining of the flagella, or locomotor organs of motile bacteria.

There are other books on bacteriological technique in English which better serve the purpose for which this one is intended.

## DEGENERACY IN LITERATURE.

The recent epidemic of Yellow Books, Green Carnations, and New Women in England has led Mr. Charles Dudley Warner to descant, in his own charming way, upon the "yellows" in literature, and to recommend scientists, alienists, and psychological investigators to study it, believing that it signifies disease. A study of the sort was made some years ago, before the works above mentioned appeared, by Max Nordau, whose work,[1] an English translation of which has just appeared, has naturally given rise to much criticism.

Nordau was well equipped for the task. In the first place he had been a literary critic for many years, and was thoroughly familiar with modern literature; and, in the second place, he was a disciple of Lombroso, to whom he dedicates his book, and, although not a physician, he had studied neurology and psychiatry very thoroughly, and he was familiar with the morbid mental phenomena of hysteria, insanity, degeneracy and crime. With such a mental equipment, then, which few mere critics could possess, he gives himself to the investigation of certain modern tendencies in art and literature, and to a careful diagnosis of the mental condition of some of the writers who are looked upon by many as leaders in modern thought. As a result he finds that these tendencies have their sources in the degeneracy of their authors, and that the enthusiasm of their admirers is for manifestations of more or less pronounced moral insanity, imbecility, and dementia.

Such a study has a special interest for the physician. It might seem at first that the interest would be pathological rather than therapeutic, for it is hard to believe that Mr. Aubrey Beardsley or Mme. Sarah Grand, for instance, would wish to be cured of the morbid manifestations which are their chief title to fame. Nevertheless, if books or works of art inculcate absurd and anti-social doctrines, they exert a disturbing and corrupting influence on the minds of many people, especially the weak-minded and hysterical, and those who adopt every new doctrine which they think is fashionable. We have seen within a few months how much mischief a degenerate labor agitator can do if chance puts him into a position of power. The neurotic are often rendered much more unstable and sometimes actually insane by dwelling too much upon the teachings of the degenerate, whether it be in the field of anarchy, socialism, theosophy, Christian science, or spiritualism. It therefore becomes the duty of the physician, as a matter of public mental health, clearly to recognize the mental stigmata of degeneracy, and to point out to the public the true nature of such conditions and the leading facts in mental therapeutics. Unhealthy books may do as much harm to the mind as certain disease-germs do to the body, and it is not against the so-called pornographic writers alone that the public should be warned. The physician too often gives precise directions about the preparation and ingestion of food for the body, while he too seldom considers what food is offered to his patient's mind, and yet a course of Ibsen or Tolstoi or Maeterlinck may do as much harm to some persons as devilled kidneys, Welch rabbits, or mince pie. Only by a careful study of the mental stigmata of degeneracy can the physician prescribe what Nordau calls the effective treatment of the disease of the age: "Characterization of the leading degenerates as mentally diseased; unmasking and stigmatizing of their imitators as enemies to society; cautioning the public against the lies of these parasites."

The physical stigmata of degeneracy have been fully enumerated by Morel, Lombroso, and others, and they are beginning to be mentioned in the modern treatises on nervous diseases. Nordau enters into an elaborate study of the mental stigmata, which are also well recognized by alienists and neurologists. The sensory apparatus of the degenerate may either be so irritable that a slight stimulus will give rise to a very marked response, as when a color, a bar of music, or an ordinary verse of poetry fills him with a strange thrill or shudder; or it may be so sluggish as to be aroused only by the horrible or the disgusting. In the one case he may be proud of his excitability, and consider it proof of deep appreciation; in the other he may, with equal pride, consider himself above the ordinary prejudices of humanity. With it all he is selfish, conceited, and extremely emotional. A sensation ordinarily excites many different cells in the cortex, giving rise to many associated ideas, but the healthy mind disregards the unimportant ideas thus aroused and concentrates its attention only on those which are essential. The degenerate is weak of will and incapable of fixed and prolonged attention; the unimportant ideas thus called into activity are not ignored, but fill his mind with a jumble of vague and obscure notions, which suggest strange relations. A word may thus call up other words of similar sound but with no related significance, and we have the phenomena known as echolalia. With vague and obscure ideas and unusual associations,

[1] Max Nordau, Entartung, Berlin, 1893; Degeneration, New York, 1895.

the degenerate is incapable of clear thought and often becomes a mystic, finding hidden significances and inexplicable relations in all things. In other cases, with a prevalence of insistent ideas, his own personality becomes the dominant factor in his world. In cases where the sensory apparatus requires powerful stimuli, or where sexual or other animal instincts give rise to insistent ideas, he may show evidences of sexual perversion or denounce the ordinary laws of decency and custom, and be classed as an anarchist. In other cases he may be filled with vague and impractical ideas for the regeneration of society, and preach social reform. In most cases, unhappily for society, he has a morbid desire either to talk or write, and indulges that desire constantly.

Having thus set forth the leading mental characteristics of degeneracy, which, it is needless to say, are in the main accepted, Nordau carefully studies the works of various writers and brings forward the evidence that they are degenerate. Rossetti, Swinburne, Paul Verlaine, Mallarmé, Tolstoi, Wagner, Péladan, Maeterlinck, Walt Whitman, Baudelaire, the French symbolists and décadents, Oscar Wilde, Ibsen, Zola, Nietzche, and many others; all are weighed in the balance and pronounced degenerate. In many cases there can be no question as to the justice of his criticism; apart from their writings the known facts in the lives of such men as Poe, Verlaine, Maupassant, Nietzche, and Tolstoi prove his assertions. In the main, too, although his criticism is savage, and his pleading at times special, the facts which he adduces more than substantiate his assertions.

It cannot be denied that in some cases the degenerate may possess great abilities in some directions; but he will be, as Lowell said of Poe, "three-fifths of him genius and two-fifths sheer fudge." He lacks harmony and balance; his mental development is unequal, and his influence does not advance the world, but it is always unhealthy; like Carlyle, "he leads men into the wilderness — and leaves them there."

It is the tendency of the degenerate to associate with his kind, the criminal in the Mafia, the mystic in a religion, the esthete in a cult. Around those groups cluster many neurotic persons, who suffer from "the restless seeking of the modern soul for a new ideal," who are also incapable of clear thought, and who call that deep which is only obscure, incomprehensible and absurd. When the sect is once formed, many others join simply to keep in the fashion or to seem "advanced," and with them come the social strugglers who are always eager to win money or notoriety by adopting every new fashion. Degeneracy is not necessarily, as Nordau thinks, a disease of our age, but its stigmata may be found throughout literature, in the mysticisms of the Neo-Platonists, the sentimentalism of Rousseau, or the indecencies of the Marquis de Sade. It is, however, to-day, with the dearth of great writers, much more in evidence, and it becomes the physician's duty to show that these idols of the present are false gods.

## THE TREATMENT OF TETANUS BY ANTITOXIN.

A SUCCESSFUL case of tetanus treated by antitoxin is reported by John Marriott, M.B., in the *British Medical Journal* for January 19th. The symptoms began six days after the injury,— a wound in the jaw caused by a missile from a catapult — with inability to open the mouth and difficulty in swallowing.

On the ninth day, when the patient was first seen by Marriott, the muscles of the neck and back were stiff and prominent, and there was well-marked trismus. Disinfection of the primary focus, administration of chloral, as much as could be swallowed, and physostigmine (one-one-hundredth grain) hypodermically during the next two days did not relieve the symptoms, which became gradually more aggravated, until on the fifth and sixth days there was slight opisthotonos. Two and one-half grammes of Tizzoni's antitoxin were now given hypodermically, the necessary punctures causing strong opisthotonic spasms. On the next day, the thirteenth of the disease, the patient was able to swallow a little. One gramme of antitoxin was given. The following day swallowing was easier. Speech was unintelligible, but the patient could make himself understood by writing in large jerky scrawls; one-half gramme of antitoxin was given. During the following days gradual improvement was noted; one-half to one gramme of antitoxin being given daily until the twenty-first of the disease, when none was administered. The jaws at this time were still clenched. On the twenty-second day of the disease, early in the morning during sound sleep, the jaws opened sufficiently to allow the tongue to protrude and when the patient woke the tongue was caught and firmly held. The irritation caused renewed spasms, embarrassment of respiration, cyanosis. Attempts to administer chloroform only made matters worse. Although the patient appeared to be dying, one-half grain of morphia with one-fiftieth of physostigmine was given with success in causing relaxation of the spasm and release of the tongue. Recovery from the morphia was followed by a return of the spasms, which were successfully combated by antiotxin. The case progressed to recovery, and the patient was able to sit up on the thirty-fourth day.

The second case, which terminated fatally, was one of tetanus neonatorum, treated by antitoxin. The child had been delivered by a midwife, and the disease appeared on the eighth day of life. On the fourth day of the disease it was first seen by Dr. T. Lacy Firth, who reports the case.

On the fifth day of the disease there was jaundice, the eyes were tightly closed so that the lids could not be opened. The jaws were set and the neck and spine rigid. The child could be held in a vertical position by holding the legs only. A part only of the milk introduced into the mouth was swallowed, and the attempt produced cyanosis and short feeble cries. Nutrient enemata, chloral and bromide constituted the treatment.

On the seventh day an alarming collapse took place, but passed off. Similar attacks followed on succeeding days. On the tenth day there were eight of these attacks and the child died in the evening of this day.

On the eighth day of the disease four-tenths of a gramme of antitoxin was given subcutaneously, and during the ninth day two injections of the same amount were given.

On the tenth day eight-tenths gramme was given at one dose. The total given thus was two grammes.

In the *Quarterly Medical Journal* two cases of traumatic tetanus in adults are reported, both successfully treated by antitoxin. The antitoxin treatment was begun on the ninth and third days of the disease, respectively. In both these cases repeated doses of the antitoxin were required, and improvement in the symptoms followed each dose.

It is interesting to note that in the last case, a child of six, a rash resembling measles with fever and swell-

ing of the cervical lymphatic glands appeared on the twelfth day after the discontinuance of the antitoxin.

That a similar rash has been often noticed after the antitoxin treatment of diphtheria is interesting, and points to the fact that the rash may be due to the serum itself and not to the particular antitoxin it contains. The failure of the serum in the case of tetanus neonatorum cannot be considered as indicating its unreliability, when we consider that the eighth day of the disease in a new-born child is a much later period with reference to effective treatment than it is in an adult. The possibility of complications, as suggested by the jaundice and attacks of collapse, which are not usually symptoms of tetanus, is present. Unfortunately no autopsy was allowed.

In the light of these cases, and in view of the widespread reports of the success of antitoxin in diphtheria, we think the time has come when public authorities should take into serious consideration the general problem of assuring to the profession and to the public reliable sources of supply of such antitoxins as are proved by sufficient and careful experience to be curative.

## MEDICAL NOTES.

THE CHARCOT MONUMENT. — The secretary of the committee to solicit contributions to the Charcot monument fund states that the contributions up to the present time amount to six hundred and forty-two dollars.

INTERNATIONAL CONGRESS OF GYNECOLOGY AND OBSTETRICS. — The next session of the Congress will be held at Geneva in September, 1895. It will discuss the subjects of Eclampsia, Displacements of the Uterus, Pelvic Contractions, Pelvic Suppurations, and Abdominal Sutures.

A STATUE OF DR. GROSS. — The House passed the Senate bill granting permission to the American Surgical Association and the Alumni Association of the Jefferson Medical College to erect a statue to the memory of Samuel D. Gross in Washington. The bill appropriates $1,500 for a pedestal.

THE FOUR YEARS' COURSE AT THE UNIVERSITY OF PENNSYLVANIA. — According to the *University Medical Magazine*, the extension of the medical course to four years has resulted in only a trifling reduction in the number of students. There are now 815 students in the Medical Department, 369 of these being members of the third-year class.

MEDICAL PHONOGRAPHY. — A society of medical phonographers has recently been organized in London, and publishes, under the joint editorship of Drs. Gowers and Taylor, a monthly periodical, *The Phonographic Record* of *Clinical Teaching*, which is intended to familiarize readers with the best outlines used in medical phonography, and at the same time increase their medical knowledge.

A NEW SOURCE FOR CARLSBAD WATER. — The *Münchener med. Wochenschrift* notes that the report published in several newspapers to the effect that a new thermal spring had been discovered in the Vindobona House in Carlsbad is false. The report had its origin in the fact that during the recent cold spell a water-pipe burst; the water flooded the cellar and was heated by a baking oven.

VOLUNTARY ADMISSION TO NEW YORK HOSPITALS FOR THE INSANE. — The following resolution relating to the voluntary admission of patients to hospitals for the insane was adopted at the session of the New York Medico-Legal Society of March 13, 1895. "*Resolved*, That in the opinion of this Society the adoption of a law permitting voluntary admission to hospitals for the insane of such persons as may desire treatment therein is eminently proper and desirable, and the highest interests of the insane demand the incorporation of such a law among the statutes of the State of New York."

THE MEDICAL PRACTICE ACT OF TENNESSEE. — The Medical Practice Act of Tennessee has been declared unconstitutional. The *Southern Practitioner* says it has no tears to shed over this decision, and thinks the best thing to be done is for the Legislature to repeal the whole thing and get it out of the way. Evidently the bill was badly drawn, and there should be a better one. A State without a good medical practice law in these days will be a dumping-ground for quacks and incompetents.

THE CENTENARY OF THE DISCOVERY OF VACCINATION. — The directors of the German Vaccine Institute, at Weimar, are arranging for a celebration, to be held in 1896, in commemoration of Jenner's discovery of vaccination. In connection therewith there is to be an exhibition of old and new vaccine instruments; of apparatus for the preservation of lymph, etc.; of original manuscripts on small-pox and vaccination; on the inoculation of sheep-pox and cattle-plague in pre-Jennerian days; of squibs on vaccination, of medals, portraits, and autographs of prominent inoculators, vaccinators and anti-vivisectionists, etc. — *Medical News.*
